8 **Abstract** Inverse methods are widely used in various fields of atmospheric science.  
9 However, such methods are not commonly used within the boundary-layer com-  
10 munity, where robust observations of surface fluxes are a particular concern. We  
11 present a new technique for deriving surface sensible heat fluxes from boundary-  
12 layer turbulence observations using an inverse method. Doppler lidar observations  
13 of vertical velocity variance are combined with two well-known mixed-layer scal-  
14 ing forward models for a convective boundary layer (CBL). The inverse method is  
15 validated using large-eddy simulations of a CBL with increasing wind speed. The  
16 majority of the estimated heat fluxes agree within error with the proscribed heat  
17 flux, across all wind speeds tested. The method is then applied to Doppler lidar  
18 data from the Chilbolton Observatory, UK. Heat fluxes are compared with those  
19 from a mast-mounted sonic anemometer. Errors in estimated heat fluxes are on  
20 average 18 %, an improvement on previous techniques. However, a significant neg-  
21 ative bias is observed (on average -63 %) that is more pronounced in the morning.  
22 Results are improved for the fully-developed CBL later in the day, which suggests  
23 that the bias is largely related to the choice of forward model, which is kept de-  
24 liberately simple for this study. Overall, the inverse method provided reasonable  
25 flux estimates for the simple case of a CBL. Results shown here demonstrate that  
26 this method has promise in utilizing ground-based remote sensing to derive surface  
27 fluxes. Extension of the method is relatively straight-forward, and could include  
28 more complex forward models, or other measurements.

## 1 Introduction

Inverse methods have widespread use throughout the atmospheric science community, with the fields of data assimilation and measurement retrieval from weather satellites perhaps being the most well-known application. However, such methods are not as commonly used with ground-based remote-sensing measurements, and are rare within the boundary-layer literature. Using inverse methods for small-scale applications would provide advantages: for example, the probabilistic basis of inverse modelling techniques provides well-defined errors in the results, and allows for many different measurements to be combined easily within the same model framework.

A recent example of small-scale application of an inverse method is Hogan (2007), who used a variational method to retrieve rainfall rates using measurements from a polarization radar. The variational method allowed for attenuation in the measurement to be corrected, and also enabled the identification and measurement of hail, which would previously have required a separate algorithm. There have also been attempts to assimilate Doppler lidar measurements of wind velocity and turbulence into more complex boundary-layer models. For example, Newsom and Banta (2004) used a four-dimensional data assimilation method with radial Doppler lidar measurements of wind-velocity fields and turbulence. Their aim was to provide datasets that could be used to verify large-eddy simulation (LES) results, in particular evaluating subgrid-scale turbulence parametrizations. Inverse modelling techniques have also been applied in atmospheric dispersion; Rudd et al. (2011) used a variational method to estimate the source strength and position of an atmospheric gas release as a possible tool in the case of accidental or malicious release.

In this work, we use an inverse retrieval method with a surface-based remote-sensing instrument to demonstrate a method for measuring surface sensible heat flux. Measurement of heat flux is of importance as both input and verification for numerical models of varying temporal and spatial scales, from simulations of city-scale pollution dispersion to numerical weather prediction models. However, measurements of the surface heat flux suitable for these purposes have proven difficult, in particular when considering measurements made over heterogeneous surfaces. As Cleugh and Grimmond (2001) wrote when discussing energy exchange in heterogeneous landscapes: “A current challenge in boundary-layer meteorology is to provide, either through modelling or measurements, estimates of turbulent fluxes that are representative of large regions, areas of  $10^2$ - $10^4$  km<sup>2</sup>, where the landscape is inevitably characterised by considerable surface heterogeneity”. More than a decade later, this issue still represents a problem.

The principal difficulty with making measurements of surface fluxes over heterogeneous surfaces, for example in urban areas, arises from the instruments typically used. These are traditionally surface-based point instruments such as the sonic anemometer. The low height at which such instruments are generally placed results in measurements that have a small source area. For example, the source area of a typical tower-based flux measurement (at 20-30 m) is between 0.01-1 km<sup>2</sup> (Cleugh and Grimmond, 2001), and so the flux measurements are only representative at the street scale. The placement of instruments is a problem that has limited efforts to measure and interpret urban fluxes and the urban boundary

layer, for the simple reason that it is practically difficult to place sufficiently tall measurement towers in busy cities (Roth, 2000).

An increasingly popular method to resolve this problem is the use of remote-sensing instruments. These instruments are capable of making measurements over a range from hundreds of metres to tens of kilometres, and as such make measurements that are representative of much greater areas than those made by point instruments mounted near the surface. Until recently, the resolution and reliability of surface-based remote-sensing instruments could not match the performance of the traditional methods, but advances in remote-sensing technology over the last two decades mean that long-term, high-quality measurements of turbulence are now viable. Along with a reduction in cost and an increase in commercial availability, this has seen an increase in studies and campaigns seeking to take advantage of the benefits of remote-sensing instruments; in particular their range and their ability to observe a flow without disturbing it.

Engelbart et al. (2007) reviewed some of the most common methods of using remote sensing to determine profiles of turbulent fluxes (and by extension surface fluxes) using various instruments; sodars, radio acoustic sounding systems (RASS), wind-profiling radars and lidars. They divided the methods into two categories; direct and parametric. Direct methods, as is implied, involve directly measuring fluxes using the eddy-correlation technique or by measuring variances. They require a rapid scanning instrument, or multiple beams. Parametric methods utilize simple models that relate averaged profiles of different variables to the fluxes.

A good example of the use of a parametric method was originally suggested by Angevine et al. (1994). They made measurements of the vertical velocity variance ( $\sigma_w^2$ ) in a convective boundary layer (CBL) using a wind-profiling radar, and then used mixed-layer similarity theory to relate these measurements to the surface sensible heat flux. The results using this method were compared to heat-flux measurements made with the eddy-correlation method using a sonic anemometer. Angevine et al. (1994) considered the results to be in good agreement, although there was significant scatter that they believed could be reduced through longer averaging times for the variance measurements. Their dataset was quite small, consisting of only 20 measurements, which has often been a limitation with studies using remote sensing measurements for determining surface fluxes. For example, Davis et al. (2008) successfully used a Doppler lidar to estimate surface sensible heat fluxes over Salford, Greater Manchester, but had only 12 data points.

The results of Angevine et al. (1994) are encouraging, however their method was limited by the instruments available to them at the time; the vertical range resolution of the wind-profiling radar used was 105 m, and the lowest measured gate was centred at 150 m. Also, the model they used to relate the vertical velocity variance to the surface sensible heat flux was based upon averaged measurements over a limited height range in the lower half of the boundary layer.

This paper presents a new technique for deriving surface sensible heat fluxes from boundary-layer turbulence observations using an inverse method. The method is applied to Doppler lidar observations of the profile of vertical velocity variance in a CBL. Firstly, the formalism of the inverse model and the treatment of errors is presented and secondly, the method is validated using a large-eddy simulation of a CBL with increasing values of wind shear. Well-known mixed-layer similarity theory results are used as forward models to relate variance profiles to heat flux. Thirdly, the method is applied to Doppler lidar observations over moderately het-

127 erogeneous terrain and compared with sonic anemometer heat-flux measurements.  
 128 The inverse method allows for calculation of a well-defined error in the results,  
 129 permitting a robust comparison.

## 130 2 The optimal inverse method

131 An optimal inverse method (e.g. Lorenc, 1986; Rodgers, 2000; Bannister, 2003)  
 132 comprises of two main components: a set of measurements and some parameters  
 133 to be determined. The physical processes that relate these components are repre-  
 134 sented by a forward model. Given a particular set of measurements, the forward  
 135 model can be inverted to determine an ‘optimal estimate’ of the parameters. The  
 136 method explicitly accounts for observational errors, and errors in the predicted  
 137 parameters. This section introduces the derivation of the optimal inverse method,  
 138 describes the formulation of the errors in both the measurements and the predicted  
 139 parameters, and presents two potential forward models.

### 140 2.1 The cost function

141 Following Rodgers (2000), we first define the notation of the components of our  
 142 problem. Measurements are represented by the measurement vector,  $\mathbf{y}$ , the param-  
 143 eters we wish to retrieve are represented by the state vector,  $\mathbf{x}$ , while the forward  
 144 model is denoted by the function,  $\mathbf{F}$ . The relationship between the measurements  
 145 and retrieved parameters can then be written

$$\mathbf{y} = \mathbf{F}(\mathbf{x}) + \boldsymbol{\epsilon}, \quad (1)$$

146 where  $\boldsymbol{\epsilon}$  represents any error in  $\mathbf{y}$ .

147 It is assumed that the observations can be described by a Gaussian distribution,  
 148 with an associated mean and variance. Bayes theorem can then be used to define  
 149 a cost function,  $\mathbf{J}$

$$2\mathbf{J} = (\mathbf{y} - \mathbf{F}(\mathbf{x}))^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{F}(\mathbf{x})), \quad (2)$$

150 where  $\mathbf{R}$  is the error covariance matrix (of size  $n \times n$ ) for the measurements. If  
 151 the errors in the measurements are independent, this matrix is diagonal, with off-  
 152 diagonal elements equal to zero. In this study, we assume that we possess no a  
 153 priori knowledge of the state vector. The cost function is then minimized to find  
 154 the optimal estimate of the state vector,  $\hat{\mathbf{x}}$ , which is now considered.

### 155 2.2 Finding the optimal estimate

156 In Bayesian terms, the minimum of the cost function is the same as the maximum  
 157 of the posterior probability distribution  $P(\mathbf{x}|\mathbf{y})$ , i.e. the most probable value of the  
 158 state vector given a set of measurements. In reality,  $P(\mathbf{x}|\mathbf{y})$  may be asymmetric  
 159 and have multiple peaks, making a solution difficult to find. It is reasonable to

160 assume  $P(\mathbf{x}|\mathbf{y})$  to be Gaussian (Rodgers, 2000, p. 84), thus the mean value of the  
 161 distribution will provide our best estimate.

162 To find the minimum of the cost function we equate the derivative of Eq. 2 to  
 163 zero, resulting in the following equation that is solved for  $\mathbf{x}$

$$\nabla_{\mathbf{x}}(\mathbf{2J}) = -[\nabla_{\mathbf{x}}\mathbf{F}(\mathbf{x})]^T\mathbf{R}^{-1}[\mathbf{y} - \mathbf{F}(\mathbf{x})] = \mathbf{0}. \quad (3)$$

164 Most inverse problems in the atmosphere can be described as moderately non-  
 165 linear i.e. the forward model is non-linear and the prior information does not have  
 166 a Gaussian distribution, but the errors can be described using Gaussian statistics  
 167 (Rodgers, 2000, p. 81). For a moderately non-linear forward model, the zero in  
 168 the gradient of the cost function can be found using the Gauss-Newton iteration  
 169 method, which for the equation  $f(x) = 0$  can be written:  $x_{k+1} = x_k - f(x_k)/f'(x_k)$ ,  
 170 where  $k$  represents the iterative step and in this case,  $f(x)$  is the first derivative  
 171 of the cost function (Rodgers, 2000, p. 85). The iterative formula is then

$$\mathbf{x}_{k+1} = \mathbf{x}_k + \mathbf{A}^{-1} \left( (\mathbf{F}'(\mathbf{x}_k))^T \mathbf{R}^{-1} (\mathbf{y} - \mathbf{F}(\mathbf{x}_k)) \right), \quad (4)$$

172 where  $\mathbf{A}$  is the Hessian matrix, which is the second derivative of the cost function

$$\mathbf{A} = \mathbf{F}'(\mathbf{x}_k)^T \mathbf{R}^{-1} \mathbf{F}'(\mathbf{x}_k) - \mathbf{F}''(\mathbf{x}_k)^T \mathbf{R}^{-1} [\mathbf{y} - \mathbf{F}(\mathbf{x})]. \quad (5)$$

173 The second term on the r.h.s. of  $\mathbf{A}$  contains the second derivative of the forward  
 174 model,  $\mathbf{F}''(\mathbf{x})$ . This term is small in the moderately non-linear case and becomes  
 175 smaller with successive iterations, and so can be neglected (Rodgers, 2000, p. 85).  
 176 The iterative process is repeated until the solution converges satisfactorily.

### 177 2.3 The error estimate in the posterior

178 The best estimate of the state vector,  $\hat{\mathbf{x}}$ , has the maximum probability  $P(\hat{\mathbf{x}})$ . An  
 179 estimate of the error in  $\hat{\mathbf{x}}$  is the variance of the probability distribution,  $\sigma^2$ . To  
 180 find this variance, we first write the posterior distribution as a Gaussian function

$$-2\ln P(\mathbf{x}|\mathbf{y}) = (\mathbf{x} - \hat{\mathbf{x}})^T \hat{\mathbf{S}}^{-1} (\mathbf{x} - \hat{\mathbf{x}}) + c_0, \quad (6)$$

181 where  $\hat{\mathbf{S}}$  is a covariance matrix that contains the variance of the distribution and  $c_0$   
 182 is a component of the Gaussian distribution that correctly normalizes the probabilit-  
 183 ity distribution. By equating like terms from Eq. 2 and Eq. 6, which are quadratic  
 184 in  $\mathbf{x}$ , we can show that (Rodgers, 2000, p. 25)

$$\hat{\mathbf{S}}^{-1} = \mathbf{F}(\mathbf{x})^T \mathbf{R}^{-1} \mathbf{F}(\mathbf{x}) + \mathbf{B}^{-1}, \quad (7)$$

185 where  $\mathbf{B}^{-1}$  is the associated posterior covariance matrix. This function is the same  
 186 as the Hessian matrix ( $\mathbf{A}$ ) without the second derivative term, as defined in Eq.  
 187 5, which is useful as the error estimate in  $\hat{\mathbf{x}}$  has therefore already been calculated  
 188 as part of the iteration method.

---

189 2.4 The forward models

190 For a CBL, the simplest forward model relates observations of vertical velocity  
191 variance,  $\sigma_w^2$ , to the convective velocity  $w_*$ , which represent  $\mathbf{y}$  and  $\mathbf{x}$  respectively.  
192 We consider here two different examples of such mixed-layer scaling, the first of  
193 which was developed by Lenschow et al. (1980)

$$\frac{\sigma_w^2}{w_*^2} = c_1(z/z_i)^{2/3}(1 - c_2z/z_i)^2, \quad (8)$$

194 where  $c_1$  and  $c_2$  are empirically derived co-efficients. Lenschow et al. (1980) found  
195 that this relationship fitted well to measurements from the Minnesota experiment  
196 (Kaimal et al. (1976)), as well as the numerical model results of Deardorff (1970),  
197 and it has since been used extensively to verify observation datasets (e.g. Young  
198 1988; Roth 2000; Chai and Lin 2004; Hogan et al. 2008).

199 Sorbjan (1988) proposed a function that was decomposed into a non-penetrative  
200 part (which describes the free convective processes taking place from the ground  
201 upwards) and a residual part (which describes the difference between the non-  
202 penetrative, free convection and the penetrative convection that accounts for en-  
203 trainment). The two components are then combined to give

$$\frac{\sigma_w^2}{w_*^2} = c_b(z/z_i)^{2/3}(1 - z/z_i)^{2/3} + c_t R^{2/3}(1 - z/z_i + D)^{2/3}(z/z_i)^{2/3}, \quad (9)$$

204 where  $c_b$  and  $c_t$  are constants,  $R$  is the ratio of the temperature fluxes at the top  
205 and bottom of the layer and  $D = \Delta/z_i$  is the ratio of the depth of the entrainment  
206 zone,  $\Delta$ , to the depth of the mixed layer. In Sorbjan (1990),  $c_b = 1.1$  was found  
207 using tank experiments.

208 Preliminary experiments showed that when using Eq. 9 as a forward model,  
209 the optimal inverse method would only work sporadically. This is probably due to  
210 the function being too non-linear, meaning that the cost function was too difficult  
211 to solve using a Gauss-Newton iteration. As such, the second term in Eq. 9 was  
212 neglected, i.e. representing only non-penetrative convection.

213 Excluding the penetrative part of the function implies that entrainment pro-  
214 cesses are not considered, and hence the negative entrainment flux at the top of  
215 the boundary layer is not included in this forward model. Consideration of the  
216 penetrative part of the Sorbjan function shows that  $w_*^2$ , and therefore the heat  
217 flux, is inversely proportional to the magnitude of the dimensionless vertical ve-  
218 locity variance. Inclusion of the penetrative part of the Sorbjan function would  
219 therefore result in lower values of the estimated heat flux.

220 More generally, consideration of both forward model functions shows that  
221 the surface heat flux is proportional to  $\sigma_w^3$ , and is inversely proportional to the  
222 boundary-layer height. This suggests that the estimated heat flux will be more  
223 sensitive to errors in the measured  $\sigma_w^2$  than to errors in  $z_i$ . In our implementation  
224 we have not chosen to incorporate  $z_i$  observations.

**Table 1** Specifications of the Doppler lidar operation

### 225 3 Characterizing errors in the observations

226 The Doppler lidar used in this work, which was developed by Halo Photonics,  
 227 is a coherent, heterodyne system. Specifications of the lidar operation are shown  
 228 in Table 1, and a full description of an identical instrument constructed by Halo  
 229 Photonics and its performance is given in Pearson et al. (2009). The measurement  
 230 integration time of the lidar is 32 sec, which is insufficient to capture the smallest  
 231 scales of turbulence, and so a technique is used to estimate the un-sampled vertical  
 232 velocity variance in which the inertial sub-range of the velocity measurements is  
 233 extrapolated at the highest frequencies (e.g. Bouniol et al. (2004) and Hogan et al.  
 234 (2008)).

#### 235 3.1 Assessing the errors in wind-velocity measurements

236 Pearson et al. (2009) and O'Connor et al. (2010) describe how the theoretical per-  
 237 formance of the Doppler velocity estimation can be calculated. The dimensionless  
 238 value  $\alpha$  characterizes the ratio of the photon count to the speckle count as shown  
 239 by O'Connor et al. (2010):

$$\alpha = SNR / [(2\pi)^{1/2}(\Delta v/B)], \quad (10)$$

240 where  $SNR$  is the wideband signal-to-noise ratio,  $\Delta v$  is the signal spectral width  
 241 (i.e. the bandwidth of the emitted laser beam) and  $B$  is the bandwidth of the re-  
 242 ceiver. For this instrument,  $\Delta v \approx 1.5 \text{ m s}^{-1}$  (Pearson et al., 2009). The theoretical  
 243 standard deviation of a Doppler velocity estimate for a weak signal regime,  $\epsilon_w$ , is  
 244 given by Rye and Hardesty (1993), who showed it to be:

$$\epsilon_w = \left( \frac{\Delta v^2 \sqrt{2}}{\alpha N_p} (1 + 1.6\alpha + 0.4\alpha^2) \right)^{1/2}, \quad (11)$$

245 where  $N_p$  is the accumulated photon count by the detector. This is calculated as

$$N_p = (SNR)Mn, \quad (12)$$

246 in which  $M$  is the number of data points per range gate and  $n$  is the number of  
 247 pulses averaged to make the velocity estimate.

248 The error in the Doppler velocity measurement is used to calculate the in-  
 249 strumental error in a measurement of the vertical velocity variance. This error is

250 calculated using the method of Gal-Chen and Xu (1992). We define the standard  
251 deviation of the error in the variance,  $\sigma(\epsilon_{\sigma_w^2})$ , as

$$\sigma(\epsilon_{\sigma_w^2}) = 2\sigma_w\sigma(\epsilon_w), \quad (13)$$

252 where  $\sigma_w$  is the standard deviation of the Doppler velocity estimates and  $\sigma(\epsilon_w)$   
253 is the standard deviation of the errors in the Doppler velocity measurements as  
254 calculated in Eq. 11. For  $N$  measurements, the error is

$$\sigma(\epsilon_{\sigma_w^2}) = (2/N^{1/2})\sigma_w\sigma(\epsilon_w). \quad (14)$$

### 255 3.2 The sampling error

256 Lenschow et al. (1994) derive a sampling error for a time-averaged turbulent statist-  
257 tic that comprises of two parts; a systematic error that arises due to the difference  
258 between the ensemble variance,  $\langle\sigma_w^2\rangle$ , and the mean of a set of time-averaged  
259 variances,  $\overline{\sigma_w^2(T)}$ , where  $T$  is the sampling time of the measurement; and a ran-  
260 dom error that represents the scatter of the time-averaged variances about the  
261 ensemble-averaged variance, calculated as the variance of the time-averaged vari-  
262 ances,  $\sigma_{\text{var}}^2(T)$ . Many studies neglect the systematic part of the sampling error (e.g.  
263 Angevine et al. 1994; Drennan et al. 2007) as it can be significantly smaller than  
264 the random error, particularly for larger sampling times. Here, we shall include  
265 the systematic error as part of our formulation.

266 Functions for the systematic and random errors were derived by Lenschow et al.  
267 (1994), and for the vertical velocity variance the absolute errors can be written as:

$$\epsilon_{\text{sys}} = \left(1 - \left(1 - a_s \left(\frac{\tau_w}{T}\right)\right)\right) \sigma_w^2(T), \quad (15)$$

$$\epsilon_{\text{rand}} = \left(a_r \left(\frac{\tau_w}{T}\right)^{1/2}\right) \sigma_w^2(T), \quad (16)$$

268 where  $a_r$  and  $a_s$  are constants relating to the skewness (or Gaussianity) of the  
269 vertical velocity measurements, and  $\tau_w$  is the integral time scale. In the CBL,  $w(t)$   
270 is a positively skewed process, but for practical purposes the assumption is made  
271 that  $w(t)$  is Gaussian, making  $a_r$  and  $a_s$  both equal to 2. Lenschow et al. (1994)  
272 showed that these functions are good approximations within the limit  $T \gg \tau_w$ ; as  
273 a rule of thumb this is typically  $\tau_w \geq 10$ . Equations 15 and 16 are combined to  
274 give an equation for the sampling error

$$\epsilon_{\text{samp}} = \sqrt{\epsilon_{\text{sys}}^2 + \epsilon_{\text{rand}}^2}. \quad (17)$$

275 In our study, the integral time scale is calculated for each averaging period as the  
276 integral of the autocorrelation function of the vertical velocity. Typically,  $\tau_w$  is  
277 of the order of 100 sec, which is similar to values of  $\tau_w$  found by Lenschow and  
278 Wulfmeyer (2000). As a 60-min averaging period is used, this gives  $\sim T/\tau_w \geq 30$ .

---

## 4 Validation of optimal estimation method using Large-Eddy Simulation (LES) data

LES data simulating the CBL under different wind-shear conditions are used to validate the optimal inverse method, as well as provide insight into both the sampling error and the error due to the assumptions in the forward models. The measurements of individual profiles by the Doppler lidar are simulated and compared with domain-averaged statistics; these are assumed to be equivalent to ensemble-averaged statistics.

### 4.1 Description of the Large-Eddy Model (LEM)

The model used was the UK Met Office Large Eddy Model (LEM) (Shutts and Gray, 1994). Simulations were performed with increasing values of the geostrophic wind ( $u_g = 2, 5$  and  $10 \text{ m s}^{-1}$ ), referred to as runs 1, 2 and 3 respectively. The geostrophic wind is determined above the boundary-layer top where the horizontal windspeed becomes constant with height. The three runs have values of  $w_*/u_* = 10.0, 6.3$  and  $4.5$  respectively. The model domain was divided into  $100^3$  gridpoints, with a horizontal resolution of 100 m, and a vertical resolution of 30 m (similar to the gate length of the Doppler lidar). The model timestep was 4 sec (this is smaller than that of the Doppler lidar instrument used, although this does not affect our conclusions). Domain-averaged statistics were provided at each height every 30 min and include subgrid-scale turbulence. The LEM requires a spin-up time of about 1.5 hours to reach an equilibrium state, and so data in the first hour are not included in the analysis.

In order to validate the optimal inverse method, three profiles of vertical wind velocity were extracted from the model domain in a line perpendicular to the flow to simulate “virtual lidar” profiles. If we assume a typical time scale for the flow of 100 sec, and a horizontal wind speed of  $7.5 \text{ m s}^{-1}$  (as seen in the mixed layer in run 3), then the decorrelation length-scale for the flow is about 750 m. As the profiles are separated by 25 grid points, or 2500 m, then they can be considered to be statistically independent.

### 4.2 Comparison of LEM vertical velocity variance profiles with results from previous studies

Figure 1 shows the LEM normalized vertical velocity variance profiles compared with previous datasets. These include: the aircraft and tank data that Lenschow et al. (1980) and Sorbjan (1990) used to derive the forward model variance functions, along with the functions themselves; data from three LES runs with increasing model resolution ( $32^3$ ,  $64^3$  and  $256^3$  gridpoints) from Sullivan and Patton (2011); and measurements from the NOAA High Resolution Doppler Lidar (HRDL) from Lenschow et al. (2012).

The LEM profile is compared with the LES data of Sullivan and Patton (2011) to assess whether grid resolution limits the computed variance. They found that the higher-order statistics converge and become grid-independent when the resolution ratio  $z_i/(C_s \Delta f) > 310$ , where  $z_i$  is the mixed-layer height,  $C_s$  is the Smagorinsky

constant, and  $\Delta f$  is the filter cut-off scale. By considering a typical range of mixed-layer heights in the LEM simulations, from 800 to 1300 m, we find a range in resolution ratio from  $z_i/(C_s \Delta f) = 92 - 149$ . Thus, according to the criterion set by Sullivan and Patton (2011), the statistics from the LEM simulations cannot be said to have fully converged, and so the statistics will be grid-dependent. However, the LEM profile is seen to agree best with the most highly resolved run with  $256^3$  gridpoints, suggesting that the limited resolution is not significantly affecting the magnitude of the variance profiles.

The LEM profile lies within the scatter of most of the data-sets, suggesting that it is in good agreement with them. However, the Limagne aircraft data-set is notably higher than all of the other data, and perhaps should be treated with caution. The agreement between the LEM data and the Lenschow function is also very good. The peak in the Sorbjan function sits higher at  $z/z_i = 0.5$ , which is to be expected as it represents only non-penetrative convection. This gives confidence that the LEM data-set is suitable for testing the optimal estimation method with both convective boundary layer forward models.

### 4.3 Testing of the optimal inverse method

Figure 2 shows an example of the two forward models fitted to 60-min averaged variance profiles extracted from the middle of the domain of run 1. The profiles of variance are quite irregular, in particular the profile for hour 4-5 has two distinct peaks and a minimum mid-boundary layer. The sampling error in the variance profile, calculated using Eq. 17, varies between 25-35%. The Lenschow forward model fits the variance profiles well, in particular at the top and the bottom of the mixed layer where the small sampling error constrains the fit. The Sorbjan forward model does not fit the data as well, in particular due to the height of the maximum variance in the LEM data being lower than  $0.5z/z_i$ . However, the magnitude of the maximum variance of the Sorbjan forward model is similar to that of the Lenschow forward model.

The estimated values of  $Q_H$  for all runs and profile locations for both forward models are shown in Fig. 3 and statistics are shown in Table 2. The results from both forward models are very well correlated, as both forward models estimate similar values for the maximum variance. The estimated heat fluxes compare well with the heat flux input into the LEM ( $179.4 \text{ W m}^{-2}$ ), with most points agreeing within one standard deviation (calculated from the covariance matrix of the posterior as described in Sect. 2.3). However, some points do not lie within one standard deviation of the input heat flux; this spread in the results may be partially due to model error (i.e. the error in the fitted coefficients of the forward models), but also due to the fact that turbulent processes are inherently stochastic, as evidenced by the double peak variance distribution for hour 4-5 that lies outside the sampling errors.

The average heat flux over all three runs and for all three points is  $164 \text{ W m}^{-2}$  ( $\sigma = 10.2 \text{ W m}^{-2}$ ) for the Lenschow forward model, and  $180 \text{ W m}^{-2}$  ( $\sigma = 6.8 \text{ W m}^{-2}$ ) for the Sorbjan model. The overall underestimate of the Lenschow model is due to the small negative bias in the flux estimates with increasing shear. This may be due to the lack of explicit dependence on  $u_*$  in the forward model scaling. The Sorbjan model overall produces flux estimates with a greater spread,

**Fig. 1** Normalized vertical velocity variance measurements from NOAA’s High Resolution Doppler Lidar (HRDL) (thick purple line) and African Monsoon Multidisciplinary Analysis (AMMA) aircraft campaign (black dots with one standard deviation error bars), both taken from Lenschow et al. (2012); measurements from the Air Mass Transformation Experiment (AMTEX) campaign (empty circles) and Limagne (crosses) aircraft campaigns, and tank data also from the AMTEX campaign (grey squares), all taken from Sorbjan (1991); the normalized, domain-averaged vertical velocity variance from the LEM (thick black line); the Lenschow (thin blue line) and Sorbjan (thin red line) variance functions; and normalized, domain-averaged profiles of vertical velocity variance for LES runs with resolutions of  $32^3$ ,  $64^3$  and  $256^3$  from Sullivan and Patton (2011) (dotted, dash-dotted and solid thin grey lines respectively).

367 perhaps reflecting its poorer fit, but shows no significant trend with increasing  
 368 shear. For both models the error in the flux estimates, and spread of the estimates  
 369 themselves, reduce with increasing shear due to the reduction in  $\tau_w$  with less  
 370 convective conditions. Overall, the forward models give reasonable estimates for a  
 371 CBL with increasing shear, thus justifying a simpler formulation based on purely  
 372 mixed-layer scaling when combined with the optimal inverse method.

373 In conclusion, the optimal inverse method has worked well in retrieving heat  
 374 fluxes in agreement with the heat flux input into the LEM. The estimated uncer-  
 375 tainty in the heat fluxes captures most of the variability around the true value.  
 376 The forward models themselves are relatively robust under increasing shear, the  
 377 small negative bias in the Lenschow model results at this stage would not jus-  
 378 tify the addition of  $u_*$  to the model. This gives confidence in retaining the model  
 379 formulation when applying this method to data measured in a real CBL, where  
 380  $w_*/u_*$  varies.

**Fig. 2** 60-min averaged profiles of the vertical velocity variance (thick grey line) from the point number 2 of the LEM domain, for run 1. The sampling error associated with the profile of variance, calculated using Eq. 17, is shown by the thin horizontal black lines. The plots along the top row show the Lenschow forward model after fitting to the variance (thick blue line) as well as the previous iterations (dashed blue lines). Similarly, the bottom row shows the Sorbjan model fitted to the variance (thick red line) as well as the previous iterations (dashed red lines).

## 381 5 Estimating heat fluxes from full-scale data

382 The method is now tested using Doppler lidar data from the Chilbolton Observa-  
 383 tory, UK. Estimated heat fluxes are compared with those from a sonic anemometer  
 384 at the site.

### 385 5.1 Description of experimental site

386 The Chilbolton Facility for Atmospheric and Radio Research (CFARR), is located  
 387 in the county of Hampshire, UK (51.14500°N 1.43667°W). As can be seen in Fig.

Run	Lenschow			Sorbjan		
	1	2	3	1	2	3
$\overline{Q_H}$ ( $\text{Wm}^{-2}$ )	184.2	162.4	142.4	213.0	177.2	157.2
$\delta(Q_H)$	0.19	0.15	0.17	0.23	0.13	0.16
$\sigma(Q_H)$ ( $\text{Wm}^{-2}$ )	30.0	24.5	20.3	32.0	24.4	20.1

**Table 2** The mean estimated heat flux, relative error and mean standard deviation for the three runs with each forward model.

**Fig. 3** The surface sensible heat fluxes estimated using the inverse method with the profiles of simulated lidar measurements from the LEM. Results when using the Lenschow forward model are shown in blue, results when using the Sorbjan forward model are shown in red. The results for all three independent profiles are plotted on top of the heat flux prescribed in the LEM (thick grey line), with vertical error bars indicating one standard deviation as calculated using the inverse method.

388 4, the area surrounding the observatory is predominantly rural with two potential  
 389 sources of significant inhomogeneity: Chilbolton village, which is situated roughly  
 390 700 m to the north, and a wooded area approximately 1 km to the west alongside  
 391 the banks of the river Test. The lidar is mounted at approximately 1.5 m on the  
 392 wall of the main building. The sonic anemometer is mounted at a height of 5 m,  
 393 approximately 200 m away on the ‘range’, which is 400 m in length with grass of  
 394 about 30-40 mm in length.

395 As the forward models used are based upon mixed-layer similarity scaling,  
 396 there are some criteria that must be met by the data in order that they are  
 397 suitable for use. The boundary layer must be convectively driven, with little or no  
 398 shear production of turbulence, and cloud cover should also be negligible so that  
 399 turbulence is mainly driven by the surface fluxes. Plots of vertical velocity and  
 400 backscatter were examined by eye between the months of May to September 2008  
 401 in order to select days with very little or no cloud cover visible in the backscatter,  
 402 and when the vertical velocity shows a deep well-mixed layer during the daytime.  
 403 Unfortunately technical problems with the sonic anemometer during this time  
 404 period limited the number of days available for analysis. Thirteen days were found  
 405 in total: the 6, 7, 8, 11 and 12 May, the 7, 8, 9, 17 and 19 June, the 30 July, and  
 406 the 26 and 28 September. Measurement data between the hours of 0900 and 1700

**Fig. 4** The upper part of the figure shows a satellite image of the area surrounding the Chilbolton Observatory. Chilbolton Village is circled to the north of the Observatory site, and the River Test, which is surrounded by woodland, is labelled to the west. The lower part shows a magnified image of the observatory site as indicated by the dashed white rectangle. The locations of the Doppler lidar and the sonic anemometer are indicated; the concentric rings show distances in steps of 200 m centred upon the lidar location. ©Google Imagery, 2011.

407 UTC were examined for these days; during these times values of  $w_*/u_*$  ranged  
 408 between 1.8 and 8.9, with an average value of 3.6.

#### 409 5.2 Profile fits for a typical day

410 Figure 5 shows the forward models fitted to the variance profiles on 7 May 2008.  
 411 The diurnal evolution of the CBL is evident, with maximum variance and deepest  
 412 mixed layer occurring in the middle of the day. It can be seen that for different  
 413 time periods one forward model is generally better suited than the other i.e. the  
 414 Sorbjan function is a better fit than the Lenschow function for 1300-1400. The  
 415 optimal inverse method was occasionally unable to fit the Lenschow function to  
 416 profiles in which the measured variance profile lacks a defined peak e.g. from 0900-  
 417 1000, which resembles a neutral profile. Overall, the Sorbjan function proved more  
 418 robust, possibly due to its symmetrical shape, and could be fitted to most profiles.

**Fig. 5** Hourly plots of the measured vertical velocity variance profile measured by the lidar (thick grey line) on the 7 May, 2008 (all times are in UTC). Errors are indicated by the horizontal grey lines. The Lenschow function is indicated by the blue line, and the Sorbjan function by the red line.

### 419 5.3 Heat flux estimation for all days

420 Figures 6 and 7 show time series of heat fluxes estimated by the optimal inverse  
 421 method for all days compared to those measured using the sonic anemometer.  
 422 A clear diurnal cycle can be seen with generally good agreement with the sonic  
 423 anemometer fluxes. A negative bias for both forward models can be seen in the  
 424 mornings: this occurred when the variance profile was more neutral in shape (i.e.  
 425 monotonically decreasing) as shown in Fig. 5. Occasionally, mid-day fluxes are  
 426 extremely large, and inconsistent with periods before and after. These were due  
 427 to large spikes in variance observed by the lidar in the middle of the boundary  
 428 layer, rather than smooth peaks, to which the models were fitted. These estimates  
 429 therefore seem unphysically large and are treated as outliers.

430 The methodology of Willmott et al. (1985) is used to calculate the systematic  
 431 and non-systematic root-mean-square errors ( $RMSE_{sys}$  and  $RMSE_{nonsys}$  respec-  
 432 tively) for the afternoon results.  $RMSE_{sys}$  describes the linear bias (a measure of  
 433 the underestimation), while  $RMSE_{nonsys}$  can be interpreted as the random error  
 434 (a measure of the variability) in the results.  $RMSE_{sys}$  is larger for the heat fluxes  
 435 estimated using the Lenschow function ( $-71 \text{ W m}^{-2}$ ) than those using the Sorbjan  
 436 function ( $-55 \text{ W m}^{-2}$ ), indicating a larger bias when using the Lenschow function.  
 437  $RMSE_{nonsys}$  is the same for the heat fluxes estimated using both forward models  
 438 ( $23 \text{ W m}^{-2}$ ), indicating that they both have a similar scatter in the results. This  
 439 analysis shows that the linear bias in the results constitutes the majority of the  
 440 error for this method.

**Fig. 6** Time series comparing the lidar estimated surface sensible heat flux for the two variance profile models (Lenschow model - blue line, Sorbjan model - red line) to that measured by the sonic anemometer (grey line). The vertical lines show errors in estimates of the heat flux; for the optimal estimation method it is the variance in the state vector, for the sonic anemometer it is the sampling error (NB: the error for the sonic anemometer fluxes is approx. 1% and thus not visible on graph.)

441 The relative errors in the surface sensible heat fluxes estimated by the optimal  
 442 inverse method have a median value of 17% when using the Sorbjan function,  
 443 and 18% when using the Lenschow function. Comparing with previous results,  
 444 Angevine et al. (1994) estimated a relative uncertainty of 30% in their results,  
 445 although their analysis only takes into account a parametrized sampling error in  
 446 the vertical velocity variance measurement. The only error considered in the sonic  
 447 anemometer measurements of the heat flux is the sampling error, which is very  
 448 small for these results, with the median relative error less than 1%. This is due to  
 449 the relatively short integral time scales measured by the sonic anemometer, which  
 450 are of the order of 1 s, compared to the integral time scales measured by the lidar,  
 451 which are of the order of 100 sec. The shorter integral timescale is a result of the  
 452 height of the sonic anemometer: the proximity of the instrument to the ground  
 453 limits the size of the turbulent eddies that it is measuring.

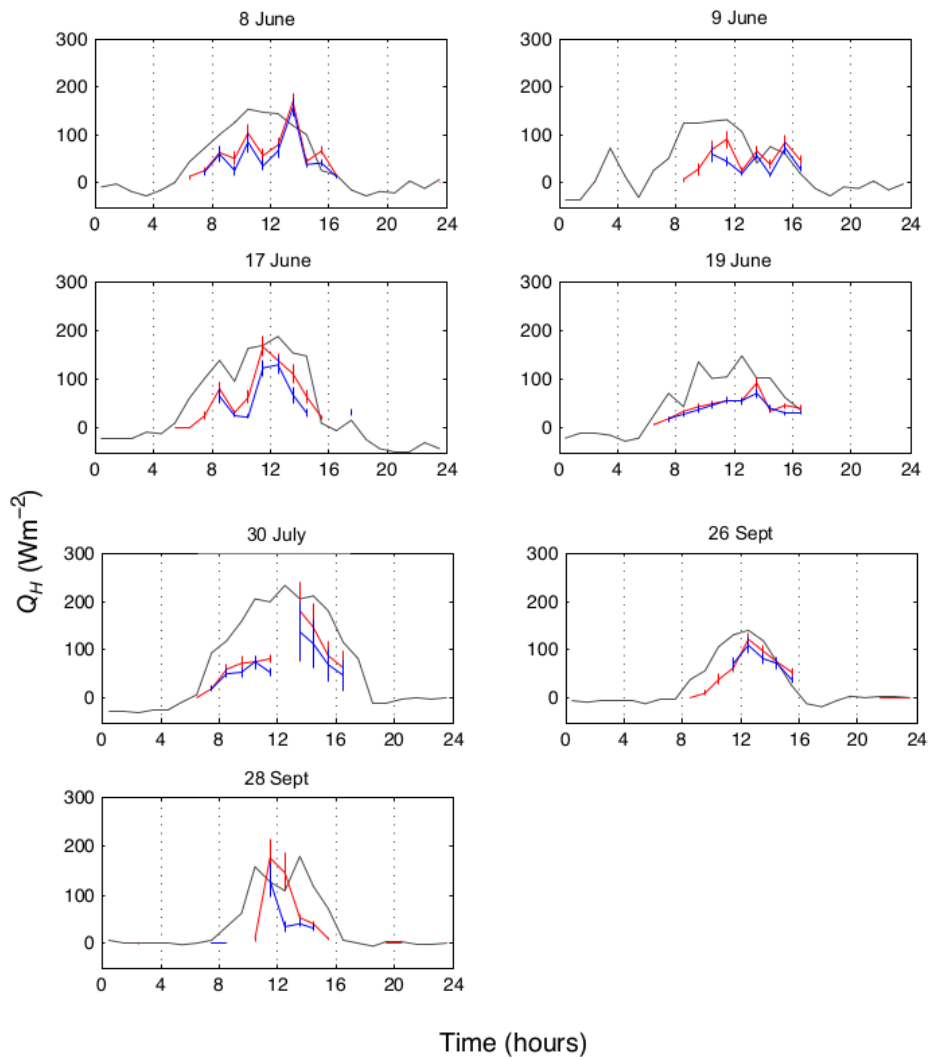

Fig. 7 As for Fig. 6.

#### 454 5.4 Exploring the scatter and bias in the results

455 There are several possible explanations for the bias between the heat fluxes esti-  
 456 mated using the optimal inverse method and those measured by the sonic anemome-  
 457 ter that are now explored.

458 1) Due to the limited sampling rate, the lidar may still underestimate the  
 459 vertical velocity variance, and thus the heat flux, despite the use of the inertial  
 460 sub-range extrapolation technique (as mentioned in Sect. 3). This is unlikely as the  
 461 measurements are made in the daytime, when the underestimation of the variance

**Fig. 8** (a) Profiles of variance measured by the lidar between 0900 and 1000. Profiles from individual days are shown by the thin grey lines. (b) Profiles measured between 1000 and 1100. (c) Profiles measured between 1100 and 1200.

462 by the lidar is minimized due to the large size of the turbulent eddies. However,  
 463 underestimation due to spatial averaging over each 30 m range gate has not been  
 464 explored.

465 2) The optimal inverse method may be overestimating the mixing height, which  
 466 is part of the predicted state vector, and thus underestimating the heat flux due  
 467 to the inverse relationship between  $z_i$  and  $Q_H$ . The estimated mixing heights using  
 468 both forward models ( $z_{iS}$  for the Sorbjan function and  $z_{iL}$  for the Lenschow  
 469 function) were compared with heights calculated using the vertical velocity vari-  
 470 ance threshold method described in Barlow et al. (2011). This method involves  
 471 defining a ground-based turbulent layer of depth  $z_{iV}$  in which  $\sigma_w^2 > 0.1 \text{ m}^2 \text{ s}^{-2}$   
 472 at all heights. On average, the mixing height estimated using the Lenschow for-  
 473 ward model is 215 m higher than that estimated using the Sorbjan forward model,  
 474 which is consistent with the Lenschow function producing negatively biased heat  
 475 fluxes. However,  $z_{iL}$  is closer to  $z_{iV}$ :  $z_{iL}$  is on average only 37 m lower than  $z_{iV}$ ,  
 476 whilst  $z_{iS}$  is 252 m lower than  $z_{iV}$ . This suggests that the optimal inverse estimate  
 477 of mixing height using the Lenschow function is not overestimated, and therefore  
 478 does not explain the underestimation of heat fluxes.

479 3) Differences in the source areas of the two instruments may be causing a bias  
 480 between the heat fluxes. Approximately 200 m to the south of the sonic anemome-  
 481 ter are some buildings which may be drier and warmer than the surrounding  
 482 vegetation. If they lie within the source area of the sonic anemometer, which is  
 483 smaller than for the lidar due to the lower measurement height, the measured heat  
 484 flux may be larger than that calculated using the lidar measurements. The heat  
 485 fluxes measured using the sonic anemometer showed no significant relationship  
 486 with wind direction, i.e. were not anomalously large when the wind direction was  
 487 aligned with the buildings. We conclude that differences in the source areas do not  
 488 explain the negative bias in lidar-derived fluxes.

489 4) Fig. 8 shows the variance profiles measured by the lidar in the morning for  
 490 each hour between 0900 and 1200. It is clear from plot a) that between 0900 and  
 491 1000 most of the variance profiles are monotonically decreasing. Between 1000 and  
 492 1100, and 1100 and 1200, most of the variance profiles are similar in shape to the  
 493 forward models (i.e. they possess a peak in the middle of the boundary layer).

494 Sonic anemometer measurements of  $w_*/u_*$  in the morning ranged between 1.5  
495 and 5.2 with an average value of 2.7 between 0900 and 1000. These values suggest  
496 that the layer is convectively unstable whereas the measured profiles of variance  
497 were neutral in shape (i.e. monotonically decreasing). Beare (2008) studied the role  
498 of shear in the morning transitional layer using an LES, simulating a CBL growing  
499 within a stable layer. He showed that during the early stages of the growing CBL,  
500 the turbulent kinetic energy budget of the layer is still dominated by shear, giving  
501 a mixed “convective-stable” state of the boundary layer. The classic CBL state,  
502 dominated by buoyancy, is only reached after several hours of simulation, when  
503 the previous night’s residual layer has been completely eroded by thermals. These  
504 results suggest that the chosen forward models may not be appropriate for use in  
505 the early morning when boundary layer structure is more complex and shear may  
506 be playing a dominant role. Beare (2008) suggested scaling to account for this  
507 effect, which could form the basis of a more sophisticated forward model in future  
508 development of the present work.

## 509 6 Conclusions

510 We have presented a novel technique that uses an optimal inverse method with  
511 Doppler lidar measurements of turbulence to estimate the surface sensible heat  
512 flux. This is the first time such a method has been used for a small-scale boundary-  
513 layer application. The heat fluxes estimated using this method are assumed to have  
514 an effective source area of tens of  $\text{km}^{-2}$ , and thus the inverse method for estimat-  
515 ing fluxes may be more appropriate over heterogeneous surfaces than traditional  
516 point measurement methods, such as those that use sonic anemometers, which  
517 have a smaller source area.

518 The simple case of a CBL with a homogeneous surface heat flux was chosen to  
519 test the optimal inverse method. Two forward models of mixed-layer scaling were  
520 chosen to relate vertical velocity variance to surface heat flux, namely Lenschow  
521 et al. (1980) and Sorbjan (1990). The error covariance matrix for the Doppler  
522 lidar observations of vertical velocity variance was derived as a combination of  
523 instrumental and sampling errors. The error in the estimated state vector (in  
524 this case the surface heat flux) was derived by assuming the posterior probability  
525 function to be Gaussian.

526 Firstly, the method was tested using an LES of a CBL with constant surface  
527 heat flux and three runs with increasing geostrophic wind speed. Three independ-  
528 ent “virtual lidar” profiles were taken across the domain and used with the inverse  
529 method, the error based solely on sampling considerations. The optimal inverse  
530 method successfully fitted the forward models to the LES variance profiles, and  
531 the majority of the estimated heat fluxes agreed within error with the input heat  
532 flux. The estimated heat fluxes varied little with increasing wind speed, suggest-  
533 ing that the forward models in this case were relatively robust and did not require  
534 explicit inclusion of the effect of shear.

535 Secondly, the optimal inverse method was applied to Doppler lidar data from  
536 the Chilbolton Observatory, UK, which lies in relatively flat terrain with mod-  
537 erately heterogeneous land use. Estimated heat fluxes were compared with those  
538 from a sonic anemometer mounted at a height of 5 m. The comparison showed  
539 that the optimal inverse estimates were linearly correlated with the point mea-

surements with a degree of scatter ( $23 \text{ W m}^{-2}$ ) and a significant negative bias:  $-71 \text{ W m}^{-2}$  for the Lenschow model and  $-55 \text{ W m}^{-2}$  for the Sorbjan model. As the bias was more pronounced in the morning, it was noted that variance profiles at that time tended to lack a peak, instead decreasing monotonically with height, despite a large surface heat flux. In these cases the forward models would be successfully fitted to the data, despite the profile being “shear-like” rather than “convective-like”, resulting in a reduced heat-flux estimate. Extending the forward model to include surface-layer scaling (i.e. the friction velocity) might be a solution to this issue. The heterogeneity of the site, given the difference in source areas for the sonic anemometer and the lidar, was considered: a positive bias in sonic anemometer-derived heat fluxes could not be found with wind direction, suggesting that this did not explain the overall negative bias of the optimal estimates. However, this result suggested that the optimal estimate method should be tested against either path-averaged or area-averaged flux data, or flux data from a truly homogeneous site.

Overall, the optimal inverse method was shown to provide reasonable flux estimates for the simple case of a CBL. Discrepancies were shown to be largely related to the choice of forward model, which was kept deliberately simple for this study. Results shown here demonstrate that this method has great promise in utilizing ground-based remote sensing observations of the boundary layer to derive surface fluxes. Extension of the method is relatively straight-forward, and could include a more complex forward model, or even independent measurements as additional constraints (e.g. boundary-layer depth).

## 7 Acknowledgements

The authors wish to thank Alan Grant for running the LEM to provide convective boundary layer simulations, and guidance in interpretation of the results. T. Dunbar was funded through a Natural Environment Research Council grant reference number NE/F00706X/1.
