Assessing the potential economic benefits to farmers from various GM crops becoming available in the European Union by 2025: results from an expert survey

3 1. Introduction

4 Evidence is being presented in many quarters that genetically modified (GM) crops have delivered net benefits for farmers, both small and large scale, and consumers, in the countries 5 6 where cultivation has been permitted (e.g. Brookes & Barfoot, 2016 and James, 2014). 7 Depending on the crop and trait, these benefits might be agronomic, economic and/or 8 environmental in nature, resulting from yield improvements, better management of pests and 9 diseases, reduced input use and nutritional improvements. While there are a growing number of commercially-grown GM crops in the world, only one GM crop is currently permitted for 10 11 cultivation in the European Union (EU) i.e. Bt maize. While Bt maize cultivation occurred in 12 five EU countries in 2014, the areas cultivated were very small, with only Spain and Portugal producing more than a few thousand hectares i.e. 131,537 ha (MAGRAMA, 2014) and 8,542 13 14 ha (Ministry of Agriculture and Sea of Portugal, 2014) respectively. As the House of Commons (2015) points out, the fact that there is only one GM crop approved for cultivation 15 is largely due to the extremely slow and cumbersome EU GM approvals process, which 16 17 requires majority member state approval in the European Council, resulting in an effective moratorium on further authorisations in the EU. As a consequence of this extremely arid 18 19 policy environment, private sector investment in GM technology has moved out of the EU 20 and consequently there is very little research being undertaken specifically focused on the needs of EU agriculture or consumers. It is, therefore, unsurprising to note that some 21 22 commercial biotech companies have started to withdraw pending applications for EU authorisations for GM technologies that they have developed (EC, 2016a). 23

25 However, this 'informal' moratorium on GM authorisations within the EU might soon 26 be lifted, as a consequence of recent changes to legislation. Directive (EU) 2015/412 of the European Parliament and of the Council of 11 March 2015, amending Directive 27 28 2001/18/EC, provides the means for the Member States to restrict or prohibit, on certain grounds, the cultivation of genetically modified organisms (GMOs) in their 29 territory, even when these have been judged by the EU's regulators to pose no risk to 30 31 human health or the environment (European Parliament and Council, 2015). Allowing Member States to unilaterally ban GM cultivation may not sound like much of a 32 33 breakthrough for GM authorizations, but the rationale for allowing Member States to 'opt out' of GM cultivation in this way, is that they will not need to block agreement 34 on GM authorisations within the European Council to maintain their own GM-free 35 36 status, thereby making EU-level authorisations easier to obtain.

37

Outside of the EU, the development pipeline continues to produce new 38 39 commercialized GM crops. The USDA Animal and Plant Health Inspection Service (APHIS), which regularly publishes lists of successful petitions for unregulated release 40 41 of GM events into the environment in the USA, announced in September 2015 that the 117th such petition, for a potato with blight-resistance (Pathogen Tolerant - PT) and 42 43 other properties, was approved for trials (APHIS, 2015). While there has been no 44 incentive for commercial biotech companies to develop crop-trait combinations targeted at agronomic conditions prevailing in Europe, Stein and Rodriguez-Cerezo 45 (2009) have noted that some GM crops already commercialized outside the EU, or 46 47 within the development pipeline, are both agronomically suitable and may offer potential benefits for farmers or consumers in the EU. With a potential unblocking of 48 49 the EU GM crop authorisation process now a distinct possibility, leading to some

countries in the EU (such as an independent post-Brexit UK) considering adoption of
GM crops, it is timely to review the GM crop-trait combinations that were currently,
or soon to be available, to identify their suitability for cultivation in the EU and
examine the nature of the benefits that they might offer to either farmers and/or
consumers.

55

56 Almost all past evaluations of the benefits offered by potential uptake of GM technologies in the EU have focussed on the farm-scale economic benefits offered by the most common GM 57 58 crops (soybean, maize, cotton and canola) and traits (herbicide tolerance [HT] and insect resistance [IR] (Kathage et al., 2016). This concentration on crop-trait combinations already 59 commercialised (see, for example, Demont and Tollens, 2004; Demont et al., 2007; Brookes, 60 61 2007; Demont et al., 2008; Dillen et al., 2009; Carpenter, 2010) has occurred for the practical 62 reason that these cases provide some data on the benefits obtained from adoption available from non-EU settings, or at least from field-scale trials. As Kathage et al. (2016) pointed out, 63 64 the availability of data remains the primary constraint to evaluation of the impacts of GM crops in the EU setting. An exception to this trend is Flannery et al. (2004) who included 65 some 'hypothetical' crop-trait combinations in a benefits evaluation for Ireland. For the 66 study detailed here, it was concluded that because the policy and regulatory changes required 67 68 to 'open up' EU member states to GM crop production was likely to take a number of years, 69 the scope of this analysis could not be confined to GM technologies already commercialised, but must also have to take into account crop-trait combinations still in development, that are 70 71 likely to be available in the near future, say by 2025.

The novel approach taken in the evaluation presented here i.e. extending the scope of the
analysis to include GM crops not yet commercialised, presented an obvious methodological
problem: that of obtaining data on the likely benefits from uptake of crops where no

75 observational data were available. Past approaches to estimate likely benefits from GM crops 76 grown in the EU have involved extensive surveys of non-EU production thus providing data for transfer into the EU context. When such approaches were not possible i.e. where only 77 78 limited data were available, modelling exercises have been undertaken (see, for example, Demont and Tollens, 2004), sometimes involving statistical approaches, such as stochastic 79 simulation techniques to overcome concerns about the accuracy or representativeness of the 80 81 data. However, for most crops considered here, because they are yet to be commercialised, no data are available at all. To overcome this problem, we adopted the only remaining 82 83 approach that could supply credible benefits data – stakeholder consultation, where a panel of experts in GM technologies provided estimates of likely future benefits of GM adoption. 84 This approach was also applied to crop-trait combinations that are commercialised outside of 85 86 the EU, as these individuals have the appropriate knowledge to make necessary adjustments 87 to non-EU data to account for differences in agronomic conditions between the data donor and recipient countries. Stakeholder consultation seemed to provide a consistent data 88 generation process for all cases i.e. for technologies already developed and those still in the 89 development pipeline whether for input or output traits. The approach: 90 91 • could be informed by any economic evaluation that exists; • could make adjustments to non-EU data to account for EU agronomic conditions; and 92 • could generate new 'notional' data where no observational data currently existed. 93 94 95 To maximise the quality of the data derived from the survey of stakeholders, the study 96 employed the so-called 'Delphi' technique, developed at the RAND Corporation (Dalkey and Helmer, 1963). The Delphi technique takes information from a panel of well-informed 97 98 individuals and builds these data into a consensus about possible future change or

developments (Hsu and Sandford, 2007; Linstone and Turoff, 1975; Martino, 1993; Young

and Jamieson, 2001). The key characteristic of the Delphi process is that data gathering is an
iterative process, punctuated by feedback of the group results to all contributing individuals.
In light of this feedback individuals are then permitted to amend their judgements until an
acceptable measure of consensus is reached. Multiple iterations are sometimes required to
derive an acceptable level of consensus. Data can be collected in a group setting, or
anonymously, as this is an effective way of reducing the biasing effects of dominant
individuals operating in group settings such as focus groups (Dalkey, 1972; Scott, 2011).

The Delphi technique has become a well-accepted means of using expert opinion to help 108 anticipate future events in many technological, social and political fields. It has also been 109 used to explore a diverse range of issues in the realm of food and agriculture, for example: 110 policy forecasting (Fearne, 1986); anticipating biotechnology trends (Menrad et al, 1999); 111 food supply chain developments (Ilbery et al, 2004); scoping the role of agriculture in flood 112 management (Kenyon et al, 2008); analysis of the drivers of past Common Agricultural 113 Policy (CAP) reform rounds (Cunha and Swinbank, 2009); examining sustainable upland 114 rural estate management (Glass et al, 2013); prioritisation of management strategies to 115 116 control zoonotic diseases (Stebler et al, 2015); and evaluation of vegetation management strategies under electric power lines (Dupras et al, 2016). 117

118

119

In this paper, we report the results of a global Delphi survey consultation into the potential agronomic and economic benefits that 12 prospective GM crop-trait combinations might offer to EU farmers and/or consumers. In addition, the paper also addresses the question of the significance of any estimated benefits identified i.e. asking the question 'how much difference would these benefits make to the competitiveness of adopters compared to non-

125 adopters?' Past experience suggests that once these technologies are licensed for use in a country, if they offer any worthwhile benefit, the vast majority of farmers quickly adopt 126 them. This assumption is based on observation of the very rapid and near complete market 127 penetration of Herbicide Tolerant (HT) canola in Canada (James, 2014). Some past studies 128 modelled the likely rate of uptake of GM technologies in various countries (e.g. Dillen et al., 129 2009) but these estimates were based on simple assumptions of the speed and nature of GM 130 131 adoption patterns of similar GM technologies in non-EU countries. As such approaches can be criticised, the simplifying assumption was made that, for each crop trait included in this 132 133 evaluation, maximum penetration had been achieved. For this reason, rather than examine the potential benefits received by individual farmers of adoption of these GM technologies, it 134 made more sense to explore the issue of the competitive advantage conferred on countries 135 136 that adopt them, compared to competitors that do not. To do this, the input and output impacts of the GM traits estimated in the stakeholder consultation were applied to standard 137 'representative' crop cost models for a selection of EU countries (see Method section for 138 more detail). In this exercise it was assumed that these GM technologies are taken up in the 139 UK and the impact of this on the competitiveness of UK production, relative to a selection of 140 northern EU countries, is assessed. The choice of the UK as the experimental platform for 141 this competitiveness analysis is made more pertinent by the recent Brexit vote in the UK. As 142 a consequence of this public vote, the UK will find itself outside of the EU GM licensing 143 144 framework and free to follow its own GM licensing policy. Recent UK governments, guided by scientific evidence, have been notably less sceptical of GM technologies than 145 governments in many EU countries and the European Commission and Parliament. It is, 146 147 therefore, likely that the effective moratorium on GM licensing seen in the EU will not be replicated in an independent UK. It would, therefore, be instructive to explore what impact 148

the adoption of GM technologies would have on the relative competitiveness of the UKagriculture sector.

151

152 **2.** Method

While there were many crop-trait combinations in the market, or under development, not all 153 of these would be suitable for EU agronomic conditions, or offer traits that would provide 154 benefits in the EU. A literature review was used to select appropriate candidates from within 155 this population of options through the identification of the need for a trait to meet a particular 156 EU agronomic challenge or, by identifying a particular crop-trait combination already 157 discussed in the literature which might offer benefits in the EU context, for example by 158 helping to overcome a common EU pest problem or climatic limitation (see Ricroch & 159 Hénard-Damave, 2016; Hefferon, 2015; De Steur et al., 2015; and the GM Foods Platform 160 (FAO, 2015)). Using these selection criteria, the EU FP7 AMIGA project team selected 161 162 relevant crop-trait combinations from three official government databases of applications for release of GM material to the environment: the USDA APHIS database of field tests of GM 163 crops (USDA, 2015); the EU GMO Register (JRC, 2015); and the Australian Applications 164 165 and Authorisations for Dealings involving Intentional Release (DIR) database (OGTR, 2015). The subset of crop-trait combinations selected is presented in Appendix 1, which classifies 166 167 crop-trait combinations into two broad types. First, those that have already secured USDA de-regulated status and therefore either have, or legally could be, commercialised, and 168 second, those still undergoing trials and awaiting de-regulation. 169

170

The traits identified in Appendix 1 are expressed as broad phenotype classes. However,
within these broad classes, several specific technologies might exist. For example, the
phenotype class HT captures multiple technologies providing tolerance to a number of

174	different herbicide compounds. Because of this, the counter-intuitive phenomenon is seen in
175	Appendix 1 that field trials are still being undertaken in a phenotype class even though some
176	representatives of that class have already achieved USDA deregulated status. Continuing the
177	use of the HT class as an example, this occurs where developers are trying to produce HT
178	crops tolerant either to different herbicides, or multiple herbicides as stacked traits. In the
179	APHIS database, not only have some individual technologies been de-regulated, but they
180	have also been commercialised, and so are currently available for uptake by farmers in some
181	countries. To illustrate, 67% of the area of maize grown in the USA in 2013 was stacked
182	herbicide tolerant/insect resistant (HT/IR) (Fernandez-Cornejo et al, 2014), while drought
183	tolerant maize was grown on 275k ha (0.3% of the total area) in the USA in 2014 (James,
184	2014).
185	
186	The shortlisted crop-trait combinations identified by means of this review process, had the
187	following characteristics:
188	• the technology had either achieved USDA de-regulated status, or was undergoing
189	field trials towards that objective, either in the USA, the EU or Australia;
189	field trials towards that objective, either in the USA, the EU or Australia;
189 190	field trials towards that objective, either in the USA, the EU or Australia;the technology is agronomically suitable for EU agriculture; and
189 190 191	 field trials towards that objective, either in the USA, the EU or Australia; the technology is agronomically suitable for EU agriculture; and examples of this technology are either already available in the global marketplace, or
189 190 191 192	 field trials towards that objective, either in the USA, the EU or Australia; the technology is agronomically suitable for EU agriculture; and examples of this technology are either already available in the global marketplace, or stand a very good chance of being so by 2025.
189 190 191 192 193	 field trials towards that objective, either in the USA, the EU or Australia; the technology is agronomically suitable for EU agriculture; and examples of this technology are either already available in the global marketplace, or stand a very good chance of being so by 2025. The subset of 12 crop-trait combinations were further classified on the basis of whether their
189 190 191 192 193 194	 field trials towards that objective, either in the USA, the EU or Australia; the technology is agronomically suitable for EU agriculture; and examples of this technology are either already available in the global marketplace, or stand a very good chance of being so by 2025. The subset of 12 crop-trait combinations were further classified on the basis of whether their traits offer benefits on the input side to the farmer or grower, i.e. improved agronomic

198 To carry out the Delphi study, a panel of stakeholders was recruited with expertise in GM issues from various professional sectors such as: crops research and development; arable 199 farming; crop protection; and farm management. Invitations to participate in the study were 200 201 sent to 212 individuals that had either been engaged in GM research i.e. authors of GMrelated papers in peer-reviewed journals, or who were participants at recent GM-related 202 conferences and technical meetings. These 212 individuals were drawn from a range of 203 204 institutional backgrounds, with the largest group being university academics (43%), followed by commercial or government research scientists (20%) and government officials (20%). In 205 206 terms of geographical location, 68% of the experts were based in Europe, 24% in North 207 America, and 8% from other parts of the world.

208

209 An explanatory recruitment letter and a one-page questionnaire were e-mailed to the panel of 210 experts in August 2015, and a reminder sent 30 days later, as a means to increase response rate. A total of 51 replies were received, 26 of which were sufficiently complete to be 211 included in the final panel (an effective response rate of 12.3%). Twenty five responses were 212 unusable, for the following reasons: 10 said they had no relevant knowledge; while 15 213 214 declined to participate for other assorted reasons. The response rate of experts working in commercial companies was much higher than for the other categories and so their weight in 215 216 the final panel is greater than in the original sampling frame.

217

Whilst the research team would have preferred to have had a Delphi panel of more than 26, we can say, without revealing confidential details of the panel, with a degree of certainty that they were very experienced and possessed expert knowledge of the subject matter under investigation. As such they were both an appropriate and relevant panel for the study.

222

223 The second round consultation document was sent out to panel members 60 days after the first mailing. In the second round, each panel member, after being reminded of their own and 224 the panel's average first round estimates, was invited to confirm or amend their original 225 226 estimates. Of the 26 panel members, 13 replied in the second round, of whom seven made 227 revisions to their first round estimates, while the remainder indicated that they were happy with their original estimates. For those who did not respond to the second round consultation, 228 229 we could only assume that they were content to retain their original estimates. Under this assumption, the sample sizes in rounds one and two remained the same. 230

231

232 While more than two iterative consultation rounds are permissible in the Delphi approach, a third estimation round was not considered useful in this case because, as elaborated in the 233 234 results section below (see Tables 1 and 2), the standard deviation scores associated with the group mean did not change significantly between rounds one and two, suggesting that further 235 significant reductions in the heterogeneity of the estimates would be very unlikely. The 236 estimates that the stakeholders were asked to make related to: (i) the impacts of the GM 237 technologies on crop yield and production costs for input-side traits; and (ii) production costs 238 and potential market price premia for the output-side traits. These estimates were expressed 239 in percentage terms, referenced against those for conventional crops in 2015. Price effects 240 241 can, therefore, be assumed to be expressed in constant price terms.

242

The analysis of the impact of these GM technologies on competitiveness was undertaken
through application of revised costs i.e. estimates by the consultees of GM impacts on yield,
production costs and product prices, as shown in Tables 1 and 2, to models of the cost of crop
production for a number of countries using a partial budgeting approach. As data for the full
costs of production were available, the impact of the uptake of GM technologies on enterprise

Net Margin was estimable. This relatively simple approach to benefits estimation, which was 248 chosen due to constraints on data availability, was adopted in several past studies which also 249 had the same relatively narrow focus on the estimation of producer economic benefits e.g. 250 251 Flannery et al. (2004). Data for these representative cost models was derived from official sources i.e. EC directorates and national Departments and Ministries of Agriculture, as well 252 as Government Agencies and commercial providers of benchmarking data. These data 253 represent country-wide 'average' costs of production for non-GM crops in the case-study 254 countries and were derived from representative survey data. 255

256

257 3. Results
```

258 3.1 Introduction

Summary results from the Delphi survey are presented in Table 1 (input-side traits) and Table
2 (output-side traits). These tables present the mean estimates from the whole panel of
consultees for both rounds of consultation, together with a measure of the change in the
variability found in these estimates from first to second round i.e. the change in standard
deviation (SD) score.

264

When SD change scores are generally negative, this implies that the SD of the sample 265 266 estimates (i.e. the extent of variation between individuals) is decreasing between rounds as 267 the panel closes in on consensus. When the SD change estimates are also small, this suggests that there is relatively little change in the SD estimates between rounds, i.e. convergence has 268 already largely been reached and that further iterations would only yield very small marginal 269 270 reductions in variation. Statistical testing, using the Paired Comparison Students' t test at the 5% level, confirmed no significant difference (p>0.05) in the variability between the mean 271 estimates of the two rounds, thus signalling no need for a further round of consultation. 272

Table 1. Experts' views on the likely effect of adopting various GM crops with input traits

287 3.2 GM crops with input traits

Input-side traits offer the prospect of financial benefits to farmers from reduced input costs, especially crop protection costs (such as less expenditure on herbicides and pesticides), and increased revenue through improved (or protected) yields. Table 1 shows that the panel anticipated cost savings from five out of seven input-side traits, but increases in production costs in the remainder. Costs savings ranged from 4.47% to 5.89%, a relatively narrow range, with these being somewhat larger in magnitude than the range of expected cost increases i.e. 0.80% to 2.38%.

295

The crop-trait combinations offering the largest savings in input costs are pathogen tolerant (PT) potato (5.89%) and HT soybean (4.93%). At the other end of the spectrum, the panel thought that drought tolerant wheat would raise farmers' costs by 2.38% due to the fact that there would be no crop protection cost savings to compensate for higher seed costs. The notion of increased production costs for drought tolerance makes perfect sense because, with the possible exception of reducing the need for irrigation, these traits do not replace any inputs, such as sprays, but they may incur higher seed costs. However, these traits may still

prove financially advantageous if their yield protection benefits, in years of drought, offsetthe higher seed costs when averaged over the longer term.

305

306 The highest and lowest anticipated yield improvements (Table 1) are both recorded for potatoes, with IR potato estimated to lift yield by 3.75%, and PT potato by 9.14%. This 307 suggests a panel consensus that current yield losses from insect pests, e.g. Colorado and Flea 308 309 Beetles, are considerably lower than yield losses from diseases, such as Brown Rot and Late Blight. It is informative to note that most of the recent GM potato trials globally have been 310 311 for late blight resistance. Drought tolerance is estimated to offer greater potential yield benefits than the average, at 8% for wheat and 6.73% for maize. These estimates are high 312 considering that they represent yield protection averaged over a number of years. This 313 314 strongly suggests the stakeholder view that yield losses in drought years might be catastrophic. Herbicide resistance traits are estimated to offer slightly below average yield 315 improvements for both sugar beet (4.19%) and soya bean (4.07%). 316

317

318 3.3 GM crops with output traits

The panel anticipated that all of the crops with output-side traits would incur increased 319 production costs compared to the conventional equivalent (see Table 2). These cost increases 320 321 would be due, almost in their entirety, to higher seed costs, as biotech companies attempt to 322 recoup their investment in product development. The stakeholder panel provided a pretty narrow range of production cost increases across crop-trait combinations, with a range of just 323 0.47%. Interestingly, the crop expected to incur the largest increases in production (seed) 324 325 costs, is wheat, i.e. 5.47% for both output traits. Here, stakeholders may be factoring in the fact that wheat is a relatively high value crop (per hectare), and so can better support higher 326

seed prices than some other crops. At the other end of the scale, the output trait with thesmallest increase in production costs was OSR with lower saturated fat content (5.0%).

329

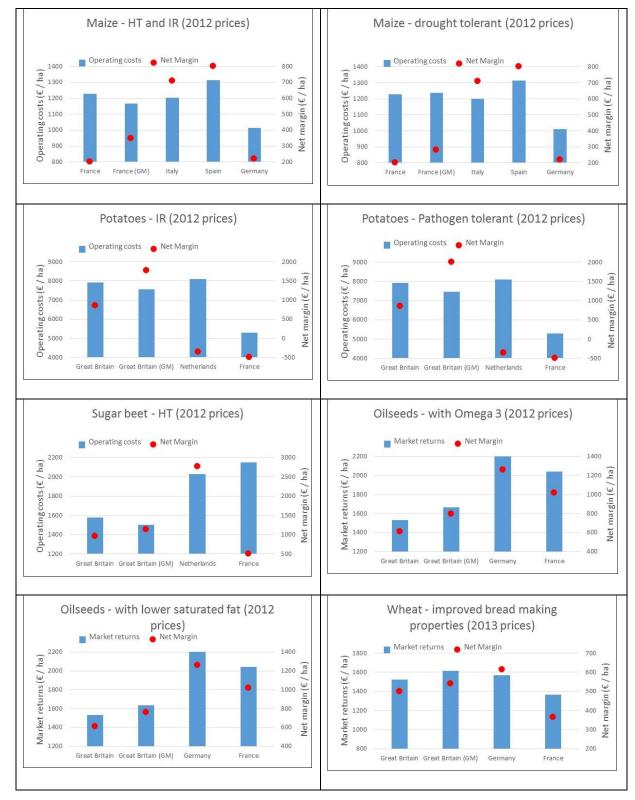

330 All of the nutritional profile changes identified for GM crops were viewed as being desirable to consumers and, so, all were expected to offer a price premium to the farmer. However, 331 they all represent niche markets so only a fairly small sub-set of farms would be able to grow 332 333 them. The highest price premium was anticipated for wheat with reduced levels of protein linked to celiac disease (9.5%), although this would only be a niche market product. Oilseed 334 335 rape producing Omega 3 oils as a dietary supplement was also expected to offer a substantial premium (8.93%). The crop with the lowest estimated premium, by comparison, was wheat 336 with improved bread making properties (6.33%). This slightly lower premium, in 337 338 comparison, may be due to the fact that the gains to bread and biscuit makers from the new properties would be only marginal, as this trait would not allow for any new differentiation in 339 the market and so a higher retail price would not be obtainable. However, the panel did not 340 give any 'hard' evidence in this respect. 341

342

343 3.4 Impact of the 'new' crops on competitiveness

The significance of these GM technologies i.e. their impact on competitiveness, was explored 344 345 by comparing GB enterprise production costs and market returns (i.e. sales value without 346 subsidy), both with and without GM, to equivalent non-GM production in selected EU countries. Figure 1 shows the impact of GM adoption on competitiveness, as expressed by 347 market returns and net margin for output-side traits, and operating costs and net margin for 348 349 input-side traits. The adopter country (i.e. where GM technologies have been applied) is GB agriculture for six out of eight crop-trait combinations, but France had to be used in the two 350 351 grain maize cases, as grain maize production does not occur in GB.

353	Figure 1 suggests that, assuming widespread adoption, the selected GM traits could improve
354	the competitive position of GB agriculture compared to non-adopting EU counterparts. The
355	way in which this improvement in competitiveness is achieved varies according to trait. For
356	input-side traits, competitiveness is improved by reducing production costs. For example, in
357	the case of potatoes, current GB production costs are roughly equivalent to those in the
358	Netherlands. However, the adoption of GM pest control technologies for this crop i.e. HT and
359	pathogen tolerance (PT) would reduce average GB production costs by 4.5% and 5.9%
360	respectively (see Table 1) to a level significantly below that in the Netherlands. If these cost
361	savings could be passed on to consumers in the form of lower prices, GB potatoes could,
362	perhaps, compete for market share in the Netherlands, despite the additional transport costs.
363	
364	In the case of output traits, the panel thought that costs of production are, more often than not,
365	expected to increase, as in the case of OSR with enhanced Omega 3 content, where
366	production costs were projected to rise by 5.2% (see Table 2). Whilst this would lead to
367	higher consumer prices if consumers placed a higher value on this 'enhanced' product, they
368	would be willing to pay these higher prices. If the monetised value that consumers placed on
369	the enhanced product was greater than the production cost increases, then a producer (price)
370	surplus would be available, as indeed is projected in this case, with an expected rise in
371	producer price of 8.9% (see Table 2). Competitive advantage would also be improved
372	through gaining access to a niche market that non-adopters could not exploit.
373	
374	Figure 1. Impact of the uptake of selected GM technologies on the competitiveness of crop
375	production in Great Britain and various EU countries.
376

(2016); and EC (2012).

381 Note: Wheat and grain maize enterprise data are based on FADN whole-farm data for farms specialising in382 those crops.

383 Note: Potato prices are based on a 3-year average centred on 2012 to smooth out extreme annual variation.

384 Note: Data originally denominated in £ Sterling have been converted to Euros, assuming an exchange rate of

385 £1=€1.2.

386 Note: NL sugar beet production costs (2012) are assumed to be the same as in DE.

387 Note: The average EU rapeseed price (2012) has been used for DE and FR.

388

389 Competitiveness is also indirectly improved, for all traits considered here, through increased profit (i.e. Net Margin). More profit means more capital is available for investment in: 390 391 technological innovation through new machinery purchases; land purchases to spread fixed 392 costs; or through enhanced training and advisory services. These investments drive increases in technical and managerial efficiency, thereby securing further improvements in 393 competitiveness. Improvement in competitiveness of this kind is best exemplified by wheat 394 with improved bread-making properties (see Figure 1). GB adoption of this GM technology 395 would increase wheat production costs by 5.5% i.e. rising above average costs in Germany, 396 but would elevate profits by 8.1% through an increased price premium (of 6.3%), thereby 397 enhancing the prospect of additional future UK investments leading to improvements in 398 399 efficiency.

400

3.5 Identification of other crop-trait GM combinations that might become available
The selection of crop-trait combinations used in the study reported here was made on the
basis that the technologies were either already in the market, or well along the development
pipeline and would also offer potentially significant benefits to EU farmers or consumers.
These particular crop-trait combinations were chosen because they captured the most
important trait types, across a range of major crops. To guard against the possibility that

408 members were asked to suggest any such alternatives that also met the selection criteria.

Only a small number of GM crop-trait combinations were suggested by the panel, these being 409 dominated by output-side traits i.e. various types of biofortification. Most of these output-side 410 411 traits would supply niche markets, which are by nature, small. Therefore, there would only be very limited opportunities to tap into these markets to secure a price premia. Such traits, 412 therefore, offer only modest benefits for the broader farming sector and wider society. In light 413 414 of this it is, perhaps, not damaging to the analysis presented here that some GM traits of this type have been omitted. Of course, some output-side traits, for example vitamin fortification, 415 416 might not be confined to niche markets but could, in theory, displace all conventional production. However, while the potential market for such traits is, in theory, very large, the 417 scale of the benefits to both farmers and wider society within the EU are likely to be small. 418 419 There are two reasons for this. First, when a GM crop displaces its conventional equivalent, 420 even if some additional societal benefit is being supplied, market prices tend to drop to the same floor as in the former conventional market. Second, in any developed country where 421 422 diets are already nutritious and where many fortified processed products already exist, the price premium for a biofortified commodity would be small, reflecting the small marginal 423 424 societal gain.

425

A minority of the panel of stakeholders, when asked to identify prospective GM technologies that were not included by our review, pointed away from traditional GM technologies instead to the products of new plant breeding techniques (NPBTs), such as CRISPR, which do not use transgenesis. Although relatively new, techniques such as CRISPR are already being hailed (for example, see Belhaj *et al*, 2013; and Ledford, 2015) as the future industry standard tool for biotechnology, thereby likely to supplant GM in plant breeding. While the status of these NPBTs are currently still being debated by advisory bodies and regulatory authorities in

the EU (Tagliabue, 2016), the hope is that because they produce plant gene modifications that
are indistinguishable from both conventional breeding and chemical and physical
mutagenesis, they will be excluded from the scope of GM legislation such as Directive
2001/18/EU on Deliberate Release of Genetically Modified Organisms. This would make
releases of such crops to the EU market much more routine.

438

439 **4. Discussion and conclusions**

Our choice of a stakeholder consultation approach for generating estimates of likely yield, 440 441 cost and revenue changes resulting from future EU (or UK) adoption of GM crops allowed a nuanced transfer of data from non-EU settings into the EU context where crop-trait 442 combinations have already been developed and has also allowed for the generation of 'novel' 443 444 data where crop-trait combinations are still in development. The extent of the challenge facing the consultees in transferring data from non-EU settings depended on several factors, 445 including perceptions of whether there are likely to be differences in seed costs, or agronomic 446 differences between the EU and non-EU settings that had to be accounted for, plus 447 differences in disease pressure and pest management practice. 448

449

Another important consideration that consultees had to account for was the likely costs 450 451 associated with required co-existence measures in adopter countries, as these could impact 452 considerably on production costs. The specific measures that might be put in place in the adopter countries for individual crops could not, perhaps, be easily anticipated, so it is not 453 exactly clear how consultees handled this issue. However, it is likely that reference would 454 455 have been made to the impact of co-existence measures on production costs in countries that had already adopted similar GM technologies. It is also worth pointing out that the existence 456 of co-existence measures in these non-EU countries has not acted either as a barrier to rapid 457

uptake, nor significantly eroded the financial benefits that the technology confers (see, for
example, Furtan et al, 2007), including the case of GM maize in Spain and Portugal.

460

461 The cross-country analysis reported here provides a useful indicator of the impacts that GM crop adoption would have on national competitiveness. However, it should be recognised that 462 this analysis presents a somewhat simplified picture of possible future adoption decisions. 463 First, the analysis assumes near complete uptake of these GM technologies in the adopter 464 country. While this must be a reasonable assumption for some of these GM technologies 465 466 based on historic observation, for example PT potatoes would likely be widely adopted as all growers could benefit. However, this might not be the reality for some crop-trait 467 combinations, for example where the GM technology targets a particular pest problem that is 468 469 not present in all regions within a country. A historical example of this would be the adoption 470 of IR maize in Portugal, where uptake has been confined to regions where European/Mediterranean Corn Borer presents a significant commercial risk (Jones et al, 471 472 2017). For crops with limited potential for market penetration, for example DT maize, the results of the competitiveness analysis should not be interpreted as indicating the impacts for 473 474 the competitiveness of the countries as a whole. 475

476 Second, the data used in the representative cost models are reflective of the central tendency 477 in each case-study country. In reality, a wide distribution of production costs exists in each 478 country, due to diversity in farmers' management ability, agronomic factors and geographic 479 location. This means that changes to the competitive advantage resulting from GM adoption 480 would not be uniformly experienced amongst producers in any country.

481

482 Third, the consultees' estimates of GM impacts in costs and yields are themselves also measures of central tendency, obscuring a likely broad range of impacts experienced by 483 individuals, where some, due to their particular circumstances, may not receive significant 484 485 benefits from the technology. Finally, the possibility must be considered that the consultees, in considering the impacts of the GM technologies on production costs, did not properly 486 factor in possible increases in costs associated with some potential negative externalities of 487 488 adoption of GM technologies, such as increase in pest resistance through the use of HT or IR events (Green & Owen, 2011; Brookes, 2014). In such circumstances, additional 489 490 management actions are required to control the problem, perhaps involving applications of alternative pesticides requiring more sprayer passes, or other approaches to pest control, such 491 492 as changed rotations, or use of deep mechanical tillage.

493

494 Whilst resistance problems can be controlled by careful use of conventional management techniques, the need to undertake them can remove some, or all, of the cost saving benefits 495 496 from the use of the technology (Green & Owen, 2011). Numerous other studies have claimed a range of environmental and social dis-benefits arising from the widespread adoption of GM 497 498 technologies, such as gene-flow to non-GM crops (Mallory-Smith & Zapiola, 2008) and wild relatives (Warwick, et al., 2008; Reichman, et al., 2006), damage to wildlife (Garcia & 499 500 Altieri, 2005) and even economic risks to non-GM producers through adventitious 501 contamination (Blakeney, 2016). There is insufficient space to critique these studies and 502 claims here, although it is worth noting that several authors have cogently argued that the environmental and socio-economic benefits of GM crops far outweigh any negative 503 504 externalities (Brookes & Barfoot, 2016). Whilst this lack of detailed critique may seem unsatisfying to some, it should be pointed out that for the analysis here there is the 505 506 requirement to do so, as the focus of the study reported here is on the impacts of adoption of

507 GM technologies in the EU on potential producer surplus, rather than consumer, or wider508 societal surplus.

509

510 The historic policy environment in the EU has resulted in an effective moratorium on GM 511 releases to the environment. With most consumers, campaigning groups and politicians across the EU remaining largely hostile to the production of GM crops and the consumption 512 of their products, it is understandable that many of the stakeholders consulted were of the 513 view that the current informal moratorium on GM authorisations would remain in place for 514 515 the foreseeable future. While the GM policy environment has changed in the last few years, there is still great uncertainty over whether this will make GM authorisations more likely, as 516 many states are likely to execute the opt-outs permissible under the new legislation. For 517 518 example, it is already known that 19 Member States had applied for the opt-out prior to the 3 October 2015 deadline for applications to the Commission, including: Germany, France, 519 Italy, Austria, Greece, Hungary, Latvia, Lithuania and Poland (New Scientist, 2015). 520 Additionally, even if authorisations begin to flow, it is not known whether GM crops would 521 actually be accepted into these national markets by retailers and consumers. 522

523

The uncertainty revealed here by our consultation over the future market and policy 524 525 environment will, of course, do little to change the attitudes of biotech companies towards 526 investment in biotechnologies targeted at EU agronomic conditions or, indeed, those seeking authorisations for GM crops to be grown in the EU. If this generally pessimistic stakeholder 527 outlook is a harbinger of restrictive future EU policies, and is a disincentive to biotech 528 529 companies to invest in GM crops targeted at EU agriculture, then the benefits associated with GM crops identified here must be viewed, in essence, as benefits that will be foregone by the 530 531 great majority of EU farmers.

In terms of the scale of these benefits foregone, the study reported here has shown that the 533 competitiveness of the agricultural sector in EU Member States could very well be improved 534 535 by adoption of GM crops. However, these improvements, when averaged over all farmers in a country, would still be relatively small-scale, to the extent that existing large-scale natural 536 advantage, resulting from relatively durable macro-economic or environmental conditions, is 537 538 very unlikely to be overturned. For example, the adoption of HT/IR grain maize in France would, in terms of country-wide averages, overturn the current small competitive advantage 539 540 that Italy holds, but would do little to eliminate the much more significant competitive advantage (resulting from lower costs of production) held by Germany. Adoption of GM 541 crops would, therefore, not be a game changer for countries with high production costs, 542 543 although they would, based on the evidence generated in the study reported here, make a positive contribution with respect to competitiveness in any country that adopts them. 544

545
