Does Twitter Predict Bitcoin?

Abstract

This paper adds to the growing literature of Bitcoin by examining the link between investor attention and Bitcoin returns, trading volume and realized volatility. Unlike previous studies, we employ the number of tweets from Twitter as a measure of attention rather than Google trends as we argue this is a better measure of attention from more informed investors. We find that the number of tweets is a significant driver of next day trading volume and realized volatility which is supported by linear and nonlinear Granger causality tests.

Keywords: Bitcoin; Twitter; Investor Attention; VAR; Granger Causality

1.   Introduction

Bitcoin has received extensive attention in the academic literature since it first introduced by Nakamoto in 2008, as demonstrated by the recent review paper by Corbet et al (2018). Bitcoin is the most popular cryptocurrency in terms of trading volume and is a peer-to- peer electronic cash system which allows online payments to be sent directly from one party to another without going through a financial institution. Therefore unlike the vast majority of other financial assets, Bitcoin have no association with any higher authority, such as a government, firm, country or commodity. Bitcoin also has no physical representation and its value is based on the security of an algorithm which is able to trace all transactions between buyers and sellers. Cryptocurrencies have received lots of media attention as well as investor attention, which is due to their low transaction costs, peer-to-peer system and governmental free design. This has led to a surge in trading volume, volatility and price of cryptocurrencies, with cryptocurrencies regularly in the mainstream news.

A strand of literature has examined whether Bitcoin returns are predictable, with Urquhart (2016) indicating that Bitcoin returns are predictable and therefore are contrary to the Efficient Market Hypothesis. This finding has been further supported by Nadarajah and Chu (2017), Tiwari et al (2018), Kjuntia and Pattanayak (2018) and Caporale et al (2018) amongst others. All of these papers examine the relationship between returns and whether there are patterns or correlations that may be exploitable by investors. A recent paper by Urquhart (2018) shows that the attention of Bitcoin, captured by Google Trends, can be explained by the previous days realized volatility and volume, indicating that the high volatility and trading volume experienced by Bitcoin number of times the term 'Bitcoin' has been searched for in the Google search engine, and therefore is a good measure of attention from uninformed individuals who want to find out more information about Bitcoin. However well-informed investors, who have knowledge of the cryptocurrency, will not be searching for it in the Google search engine but instead may be tweeting about it. These tweets may involve commenting on news posts related to Bitcoin or making predictions of the future price direction of Bitcoin or just giving an opinion of the popular cryptocurrency. Hence we postulate that the volume of Bitcoin tweets is a stronger measure of investor attention than Google Trends, which we suggest is a measure uninformed investor attention.

There is a growing literature examining the impact of Twitter on financial markets, such as Piñeiro-Chousa et al (2016), Sun et al (2016 and Piñeiro-Chousa et al (2018) who all find significant relationships between Twitter and financial markets. We add to this literature by being the first to study whether the volume of tweets involving the term 'Bitcoin' can predict the returns, volatility and trading volume of Bitcoin. This measure of investor attention should be more informed than that of Google Trends and therefore may reflect the attention Bitcoin is receiving from more informed investors. We find that the volume of tweets are significant drivers of realized volatility (RV) and trading volume, which is supported by linear and nonlinear Granger causality tests. However, we find no significant evidence that previous days tweets significantly influence the returns of Bitcoin. Therefore we add to the literature on the relationship between social media attention and Bitcoin.

2.   Data and methodology

We obtain Twitter data on Bitcoin from https://bitinfocharts.com/, which captures the number of times the term 'Bitcoin' has been tweeted and we study the period 4th September 2014 to 31st August 2018 due to data availability. We download Bitstamp exchange tick data from www.bitcoincharts.com, as it is one of the most popular and liquid Bitcoin exchanges. From the tick data, we aggregate up to the daily level and calculate logarithmic returns and trading volume. Figure 1 presents the time-series graph of the price of Bitcoin where we can see the huge surge

in price during the second half of 2017 and the subsequent falling of price during 2018. In order to measure daily RV, we aggregate the tick data up the 5-minute level such that:

$$RV_t = \sqrt{\sum_{j=1}^{N} r_{t,j}^2} \qquad (1)$$

where $r_{t,j}^2$ is squared 5-minute log returns of Bitcoin at day t during the interval j and n is the number of intraday return intervals. We calculate returns over the 5-minute frequency to avoid well-known microstructure issues while we also obtain daily volume and returns by aggregating the tick data up to the daily level. Similar to Urquhart (2018), we take the logarithmic returns, realized volatility, trading volume as well as number of tweets to avoid large skewness and excess kurtosis. Table 1 provides the descriptive statistics where the log-tweets data which shows a maximum value of 11.96 and minimum of 8.90, with positive skewness and a leptokurtic distribution. The mean is 10.32 indicating that each day, there is a sufficient number of tweets about Bitcoin during our sample period. The mean of the RV is −3.31, with quite a large standard deviation of 0.52 as well as positive skewness. The mean log-volume indicates quite high liquidity in the Bitcoin market, with a maximum log-volume of 11.73 and minimum of 6.58. Returns over our sample period are positive, with negative skewness and excess kurtosis.

To examine the dynamics between our Bitcoin variables and the number of tweets, we estimate a vector autoregressive (VAR) model, where x_t is a vector that contains the variables of interest and a VAR(k) model is:

$$x_t = c + \sum_{j=1}^{k} \beta_j x_{t-j} + \varepsilon_t \qquad (2)$$

Where c is a vector of constants and ε_t is a vector of independent white noise innovations. The lag length is determined by the Schwarz Bayesian information criterion and we estimate three separate models examining whether the volume of tweets can help predict realized volatility, trading volume and Bitcoin returns separately. From these VAR models, we employ the linear Granger causality test (Granger 1969) as well as the nonlinear causality test of Diks and Panchenko (2006). The linear Granger causality test can be expressed as:

$$\Delta x_t = \beta_0 + \sum_{i=1}^{n} \beta_{1i}\Delta x_{t-1} + \sum_{i=1}^{m} \beta_{2i}\Delta y_{t-1} + \varepsilon_{1t}$$

$$ \qquad (3)$$

$$\Delta y_t = \delta_0 + \sum_{i=1}^{n} \delta_{1i}\Delta y_{t-1} + \sum_{i=1}^{m} \delta_{2i}\Delta x_{t-1} + \varepsilon_{2t}$$

Where the lag length is determined by the Schwarz Information Criterion.[1]

3. Empirical Results

---

[1] We do not provide details of the nonlinear Granger causality test of Diks and Panchenko (2006) due to space constraints but we refer the reader to the original paper.

Table 2 reports the VAR models where the coefficient estimates are reported in Panel A and the two Granger causality results are reported in Panels B and C respectively. We can see from Model (1), which examines the relationship between RV and tweets, that the previous days tweet has a significant influence on RV indicating that higher the number of tweets, the higher the next day's RV. This is supported by the linear and nonlinear Granger causality results which both suggest that we can reject the null hypothesis that tweets do not Granger cause RV. We also find that previous day's RV has a significant influence on next day's tweets, indicating a bilateral relationship which is supported by both Granger causality tests. We also find similar results for trading volume where previous tweets have a significant impact on trading volume while both linear and nonlinear Granger causality tests support this finding, indicating that higher tweets on Twitter significantly influences the next RV, trading volume. This also find that this is bilateral relationship too where previous volume significantly influences tweets. For returns, we find weak evidence (statistically significant at the 10% level) that less tweets have a relationship next day returns, although both Granger causality tests provide significant evidence that tweets do Granger cause returns. However we do not find any significant relationship between previous returns and tweets, indicating that the link between returns and tweets is a unilateral relationship.

Therefore our initial results indicate that previous days tweets do Granger cause RV and trading volume. However the price and behaviour of Bitcoin has changed drastically over time and therefore our findings in Table 2 may not be stable over time. Therefore we split our sample into two subsamples, where the breakpoint is determined by the Bai and Perron (2003) test. The breakpoint with the greatest significance is chosen which generates are new subsample periods, which runs from 4th September 2014 to 8th October 2017, while the second subsample period spans from 9th October 2017 to 31st of August 2018. The results for the two subsample periods are reported in Tables 3 and 4 respectively where we find that in the first subsample, previous tweets have a significant effect on volume but not for RV, with both results supported by their respective Granger causality results. Consequently in the first subsample period, tweets to Granger cause volume, but not RV. However in the second subsample period, we find that previous tweets do have a significant effect on RV and volume, which are both supported by significant linear and nonlinear Granger causality results. Therefore we show that previous tweets do cause a significant increase in RV and volume the next day, which is only significant in our second subsample period.

4. Conclusion

This paper studies the relationship between the number of tweets referring to Bitcoin and whether they are useful in forecasting future RV, volume or returns. We find that the number of previous day tweets are significant drivers of Bitcoin RV and volume, but not returns. After splitting our sample into two subsample periods, we find that tweets only significantly influence volume in the first sample, but significantly influences both RV and volume in the second subsample period. Therefore we show that the number of tweets on Twitter can significantly predict future RV and trading volume of Bitcoin.
