Abstract

We present evidence that variability in the STEREO-A Heliospheric Imager (HI) data is correlated with in-situ solar wind speed estimates from WIND, STEREO-A, and STEREO-B. For 2008-2012, we compute the variability in HI differenced images in a plane-of-sky shell between 20-22.5 solar radii, and, for a range of position angles, compare daily means of HI variability and in-situ solar wind speed estimates.

We show that the HI variability data and in-situ solar wind speeds have similar temporal autocorrelation functions. Carrington rotation periodicities are well documented for in-situ solar wind speeds, but, to our knowledge, this is the first time they have been presented in statistics computed from HI images. In-situ solar wind speeds from STEREO-A, STEREO-B, and WIND are all correlated with the HI variability, with a lag that varies in a manner consistent with the longitudinal separation of the in-situ monitor and the HI instrument.

Unlike many approaches to processing HI observations, our method requires no manual feature tracking; it is automated, quick to compute, and does not suffer the subjective biases associated with manual classifications. These results suggest we could possibly estimate solar wind speeds in the low heliosphere directly from HI observations. This motivates further investigation as this could be a significant asset to the space weather forecasting community; it might provide an independent observational constraint on heliospheric solar wind forecasts, through, for example, data assimilation. Finally, these results are another argument for the potential utility of including a HI on an operational space weather mission.

Plain Language Summary

It would be useful for space weather forecasting to have a good estimate of the solar wind speed near the Sun. This could improve space weather forecasting models, and our knowledge of how the solar wind is formed and varies. However, estimating the solar wind speed near the Sun is difficult to do, with either with spacecraft that measure it directly, or with cameras observing the solar atmosphere.

We have analysed variations in images of the solar wind taken by the Heliospheric Imagers on the STEREO-A spacecraft. We show that these variations are well correlated with solar wind speed measurements taken by in-situ spacecraft. Furthermore, we show that these correlations evolve in a way that can be explained by the orbits of the spacecraft, which gives us increased confidence that that this statistical relationship is robust.

Therefore, these results might be used to develop a relationship between variability in the Heliospheric Imager data and solar wind speed, which would allow us to estimate the solar wind speed near the Sun routinely. Such a technique would be useful for space weather forecasting, and would be a good reason to put a Heliospheric Imager on any future space weather monitoring spacecraft.

1 Introduction

Effective space weather forecasting requires prediction of near-Earth solar wind conditions and hence modelling the solar wind environment of the inner heliosphere. For some time now it has been commonplace to use 3D magnetohydrodynamic (MHD) models to represent the heliosphere (such as ENLIL [Odstrcil, 2003], MAS [Riley *et al.*, 2001], and EUFORIA [Pomoell and Poedts, 2018]). Such models are driven, indirectly, by photospheric and coronal observations, as their inner boundary conditions are typically derived from the output of coronal magnetic models and empirical parameterisations (e.g the Wang-Sheeley-Argge (WSA) extrapolation of Potential Field Source Surface (PFSS) solutions of the coronal magnetic field). Several recent studies demonstrate the success of

60 this approach, with these models serving as useful research tools [Riley *et al.*, 2012], and
61 aiding skilful space weather forecasts [Riley *et al.*, 2018].

62 However, as these models do not directly use any of the available heliospheric solar
63 wind observations, an obvious question is "can solar wind observations be used to im-
64 prove MHD modelling of the space weather environment?". The answer appears to be
65 affirmative, as demonstrated by Lang *et al.* [2017], who showed that integrating a Data-
66 Assimilation (DA) scheme into ENLIL improved ENLIL's representation of the inner he-
67 liosphere. Specifically, these authors performed a theoretical experiment that showed as-
68 simulating synthetic in-situ plasma observations reduced the error of the model relative
69 to the ground truth. Furthermore, Lang *et al.* [2017] and Lang and Owens [2019] high-
70 light that it should be possible to improve heliospheric modelling by assimilating not only
71 in-situ plasma measurements, but also remote sensing observations, such as those from
72 Heliospheric Imaging instruments. Given the paucity of in-situ monitors throughout the
73 heliosphere, particularly out of the ecliptic plane, the possibility of assimilating remote
74 sensing observations of the inner heliosphere is particularly interesting, as they may pro-
75 vide information over a much broader spatial domain than in-situ monitors. We also note
76 that, alongside visible light instruments, radio observations are another complementary
77 data source that might be used in an assimilative way, through techniques such as Inter-
78 planetary Scintillation.

79 The Heliospheric Imager (HI) instruments are wide-field visible-light imagers, that
80 have routinely observed the inner heliosphere since 2007, as part of the Sun-Earth-Connection-
81 Coronal-Heliospheric-Investigation (SECCHI) instrument package aboard the twin STEREO
82 spacecraft (STEREO-A and STEREO-B) [Howard *et al.*, 2008]. The HI instruments pri-
83 marily observe sunlight Thomson scattered off free electrons in the solar wind and so, at
84 the simplest level, these observations provide a measure of the solar wind electron number
85 density along a line-of-sight (LOS) in the instruments field-of-view (FOV). A key scien-
86 tific focus for the HI observations has been characterising the evolution and propagation
87 of Coronal Mass Ejections (CMEs) through the inner heliosphere [Howard *et al.*, 2008;
88 Harrison *et al.*, 2017]. Furthermore, in the context of space weather forecasting, these data
89 led to the development of a plethora of techniques designed to predict the arrival of CMEs
90 throughout the heliosphere [Harrison *et al.*, 2017]. However, much less research has been
91 done into characterising the background solar wind structure in the HI FOV, and what this
92 may enable in a space weather forecasting context. That being said, the potential for ex-
93 tracting background solar wind information from HI observations has been demonstrated.
94 Rouillard *et al.* [2008] showed that plasma parcels entrained into Co-rotation Interaction
95 Regions (CIRs) could be imaged in HI. Subsequently, Plotnikov *et al.* [2016] tracked many
96 such events in HI images to study the long-term variability of CIRs, and whether their ar-
97 rival at Earth could be predicted from analysis of the HI images, demonstrating that they
98 typically propagate at close to the slow solar wind speed ahead of the CIR, and their ar-
99 rival near Earth can be predicted with an accuracy of several hours; these results broadly
100 consolidate those from similar but independent studies by Davis *et al.* [2012] and Con-
101 lon *et al.* [2015]. This line of research was further pursued by Sanchez-Diaz *et al.* [2017],
102 who better quantified the temporal and spatial scales of plasma blobs released into the
103 heliosphere near the heliospheric current sheet. They revealed that such blobs were re-
104 leased simultaneously across a wide range of longitudes, with a period of approximately
105 20 hours. However, although these studies have aided our understanding of the structure of
106 the solar wind in the inner heliosphere, the analysis techniques they depend upon do not
107 lend themselves to routine, global application which is required to constrain MHD mod-
108 els of the solar wind with HI observations. This is because all of these studies required a
109 large amount of manual classification in the HI observations, manually tracking features
110 associated with CMEs, and plasma blobs acting as tracers for solar wind structures, using,
111 for example, time-elongation plots (known colloquially as J-maps) [Davies *et al.*, 2009].
112 Alongside this, we also note that DeForest *et al.* [2016] presented a groundbreaking anal-
113 ysis which, through advanced processing of the HI images, revealed and quantified the

114 onset of hydrodynamic turbulence in the young solar wind. This work analysed 15 days of
115 HI1 data from December 2008 in solar minimum, and used structure function analysis to
116 quantify how the texture of the images changed with radial distance.

117 There are also a range of image processing techniques that can be used to estimate
118 the velocity of specific features within an image, or the the velocity throughout an entire
119 image, which also do not require the manual tracking of features. For example, *Pant et al.*
120 [2016] used the Hough transform to determine the kinematics of of CMEs in the HI1
121 FOV, based on earlier work by *Robbrecht and Berghmans* [2004] to develop the CACTus
122 CME catalogue from Coronagraph observations. Another branch of techniques fall under
123 banner of optical flow estimation [*Horn and Schunck*, 1981]. Optical flow techniques
124 have been used successfully within solar physics to model CME kinematics in corona-
125 graph images [*Colaninno and Vourlidas*, 2006], and chromospheric dynamics in EUV im-
126 agers [*Gissot and Hochedez*, 2007; *Gissot et al.*, 2008]. Additionally, *DeForest et al.* [2014]
127 used Fourier transforms to extract information on the flow of Alfvén waves in coronagraph
128 images of the outer corona. Our interest has focussed on describing the background solar
129 wind flow with the HI instruments, and in doing so we have experimented with different
130 optical flow estimators. However, as of yet, we have been unsuccessful in robustly de-
131 termining the background solar wind flow with these techniques, and are unaware of any
132 published works which successfully tackle this problem. From our own experiments, the
133 reduced signal to noise ratio of HI images (relative to coronagraph and EUV images) was
134 a key factor in limiting the success of this approach. Consequently, we have become inter-
135 ested in simpler and more empirical ways of constraining the background solar wind flow
136 with heliospheric images.

137 Hence, within the context of our challenges to directly estimate the solar wind flow
138 from HI images, here we explore the following question; is there is a way to process the
139 HI images that reveals aspects of the solar wind structure that might be sensibly used in
140 conjunction with a data assimilation scheme and MHD model of the solar wind. Ideally
141 such an algorithm would not require manual classification of the images, and would rely
142 on relatively simple metrics computed from the images, such that the analysis could be
143 easily integrated into a solar wind modelling workflow. We posit that variability in HI
144 differenced images can act as a tracer for solar wind structure, and demonstrate that a
145 measure of this variability has the same periodic structure as in-situ solar wind plasma
146 observations from different in-situ monitors, and can, in fact, be directly correlated with
147 in-situ solar wind plasma observations. Such an approach has promise, given the results
148 of *DeForest et al.* [2016, 2018]. In section 2 we introduce the in-situ plasma observations
149 and HI remote sensing data used throughout this investigation. Section 3 describes some
150 statistical techniques used in our analysis, while the results are presented in section 4.

151 2 Data

152 Throughout this investigation we use white-light remote sensing observations of the
153 inner heliosphere provided by the Heliospheric Imager on STEREO-A, as well as in-situ
154 observations of the solar wind plasma provided by the WIND, STEREO-A, and STEREO-
155 B spacecraft. Below we detail the provenance and processing of these data.

156 2.1 Heliospheric Imagers

157 The STEREO spacecraft, operational since late 2006, occupy approximately 1 *AU*
158 heliocentric, ecliptic orbits, one ahead of (STEREO-A: STA) and the other behind (STEREO-
159 B: STB) the Earth. Both STA and STB carry the SECCHI instrument package [*Howard*
160 *et al.*, 2008]. Included in the SECCHI package is the HI instrument [*Eyles et al.*, 2008],
161 which consists of two wide-field white-light cameras (HI1 and HI2) that image solar wind
162 structures propagating over a total elongation angle range from near 4° to around 90°
163 from the Sun. During nominal science operations, the 20° FOV of HI1 is centered at

14° in the ecliptic plane and the 70° FOV of HI2 is centered at 53.8°, also in the ecliptic plane. HI2 also includes a trapezoidal occulter, which was designed to limit the intense light from Earth at the start of the mission [Eyles *et al.*, 2008], and restricts the outer edge of the central portion of the HI2 FOV to an elongation of around 74°. Throughout this work, we use only the observations provided by the HI1 camera on STA (HI1A), over the period spanning 2008-01-01T00:00:00 until 2012-12-31T23:59:59. During this period, the nominal cadence of HI1 and HI2 science images is 40 and 120 minutes, respectively, while their binned pixel size is 70 arc-sec and 4 arc-min, respectively. More specifically, we use the Level 2, 11-day background HI1A observations, made available at <https://www.ukssdc.ac.uk/solar/stereo/data.html>. The location of features in the HI1A FOV will be discussed in terms of Helioprojective-Radial-Coordinates: position angle (ψ), the anti-clockwise angle from solar north, and elongation (ϵ), the angular distance from Sun-center.

The photons detected by the HI instrument are primarily white-light solar photons which have undergone Thomson scattering with free electrons in the solar wind. The signal received along any given line of sight in the HI FOV is an integral along that line. But, as both the density of solar wind electrons and intensity of solar photons decreases with heliocentric radius, the signal received along a sight line is biased towards photons scattered on the surface of the sphere having a diameter defined by the Sun and observer as endpoints; originally termed the Thomson Sphere (TS). However, we note that *Howard and DeForest* [2012] demonstrated that this bias was actually quite modest and also a broad function of distance along the line of sight; hence they argued it would be better referred to as the Thomson plateau.

2.1.1 HI data processing

Differenced images are produced from contiguous Level 2 11-day background subtracted HI1A images. The star fields are suppressed by identifying strong peaks in the image and replacing them with interpolated values from a 2-d cubic B-spline. Finally, a 5x5 median filter is applied to the differenced image. This is the same method as used in *Barnard et al.* [2017], and an example differenced image can be seen in Figure 1. The resulting image has a differenced image intensity field given by $I(\epsilon, \psi)$. We select a subsection of the image corresponding to the radial shell encompassing the plane-of-sky region spanning 20-22.5 solar radii, as shown by the red contours in panels A and B of Figure 1. Within this shell, we measure the differenced image variability as a function of position angle by computing the standard deviation of $I(\epsilon, \psi)$ according to

$$\gamma(\psi) = \left(\frac{(\sum_{\psi-\delta\psi}^{\psi+\delta\psi} \sum_{\epsilon_{r1}}^{\epsilon_{r2}} I(\epsilon, \psi) - (\sum_{\psi-\delta\psi}^{\psi+\delta\psi} \sum_{\epsilon_{r1}}^{\epsilon_{r2}} I(\epsilon, \psi)/N))^2}{N} \right)^{\frac{1}{2}}, \quad (1)$$

in position angle boxes 5° wide ($\delta\psi = 2.5^\circ$), centred on every degree of ψ from 60° to 120°, where ϵ_{r1} and ϵ_{r2} give the lower and upper elongation limits of the radial shell, and N is the number of pixels/samples in the position angle box. Examples of these boxes are shown for central position angles of 75°, 90°, and 105° by the blue, purple, and orange contours in panel B of Figure 1.

In Panel C of Figure 1 kernel density estimation is used to estimate the distribution of differenced image pixel brightness in the three position angle boxes marked in panel B. Kernel density estimation is a non-parametric method used to estimate a parameters distribution function from a set of observations of that parameter. Each observation is assigned a prescribed distribution function (e.g. a Gaussian) and the normalised sum of these individual distributions is assumed to be a fair representation of a parameters true distribution function [Wilks, 1995]. The vertical dotted lines beneath each distribution mark the region of $\pm\gamma$ about the mean brightness. Comparing the breadth of each $\pm\gamma$ region with the

211 corresponding kernel density estimate, we conclude that the standard deviation is a reason-
 212 able measure of variability for these distributions. To facilitate comparison of $\gamma(\psi)$ across
 213 multiple frames, we then normalise $\gamma(\psi)$ in each frame, computing the z-score

$$\gamma_z(\psi) = \frac{\gamma(\psi) - \langle \gamma(\psi) \rangle}{\sigma_\gamma}, \quad (2)$$

14 where $\langle \gamma(\psi) \rangle$ and σ_γ are the mean and standard deviation of $\gamma(\psi)$ within the radial
 215 shell in that frame. This is necessary, as the orbital motion of STEREO-A means the fixed
 216 radius plane of sky shell corresponds to elongation limits with a small annual variation.
 217 Furthermore, the intensity of HI images falls as approximately ϵ^{-3} (see *DeForest et al.*
 218 [2016]), such that $\gamma(\psi)$ tends to lower values when the elongation limits are larger. Com-
 219 puting $\gamma_z(\psi)$ provides a normalised measure of the variability in each HI frame, allowing
 220 comparison throughout the HI time series.

221 This process is completed for every viable differenced image (differenced images
 222 cannot be computed if either or both frames are missing), returning a time series of differ-
 223 enced image variability as a function of position angle, $\gamma_z(\psi, t)$. We then compute the UT
 224 daily mean of this time series, $\Gamma(\psi, t)$, averaging the $\gamma_z(\psi, t)$ values at each position an-
 225 gles for each frame within a UT day. This process is demonstrated in Panel D of Figure 1;
 226 the black line shows $\gamma_z(\psi)$ for the differenced image presented in panel A, while the grey
 227 lines show $\gamma_z(\psi)$ for all other frames obtained on 2009-06-01. The red circles show the
 228 daily mean value $\Gamma(\psi)$, with the uncertainty bars showing one standard error of the mean.

240 2.2 In-situ solar wind plasma observations

241 2.2.1 WIND

242 The WIND spacecraft has, since 2004, continuously monitored properties of the in-
 243 situ solar wind plasma whilst in a halo orbit of the Earth-Sun L1 Lagrange point. The So-
 244 lar Wind Experiment (SWE) instrument measures solar wind ion and electron properties,
 245 from which estimates of the solar wind bulk speed, density and temperature have been
 246 computed [*Ogilvie et al.*, 1995]. Here, we use the 1-hour average solar wind bulk speed,
 247 density and temperature estimates obtained from <https://omniweb.gsfc.nasa.gov/>.

248 2.2.2 STEREO-A and STEREO-B

250 The STEREO spacecraft are also equipped with the Plasma and Supra-Thermal Ion
 251 Composition (PLASTIC) instrument payload, which measures in-situ solar wind plasma
 252 properties [*Kaiser et al.*, 2008]. From these measurements, estimates of the solar wind
 253 bulk speed, density and temperature have been derived, which we use in our following
 254 analysis. Similar to the WIND data, we use the 1-hour average solar wind bulk speed,
 255 density and temperature estimates obtained from <https://omniweb.gsfc.nasa.gov/>, for both
 STA and STB.

256 2.3 Data processing

257 From the 1-hour average time series, we compute daily means of the the solar wind
 258 speed, density and temperature for WIND, STA, and STB, for every UT day in the period
 259 spanning 2008-01-01 to 2012-12-31. This results in 1828 days of samples for each param-
 260 eter, although we note that there were 2, 4, and 8 days where data availability meant valid
 261 daily means could not be computed for WIND, STB, and STA, respectively. Throughout
 262 the remainder of the article we refer to these quantities as V_x , ρ_x , and T_x , where the sub-
 263 script x takes the abbreviation of the spacecrafts name.

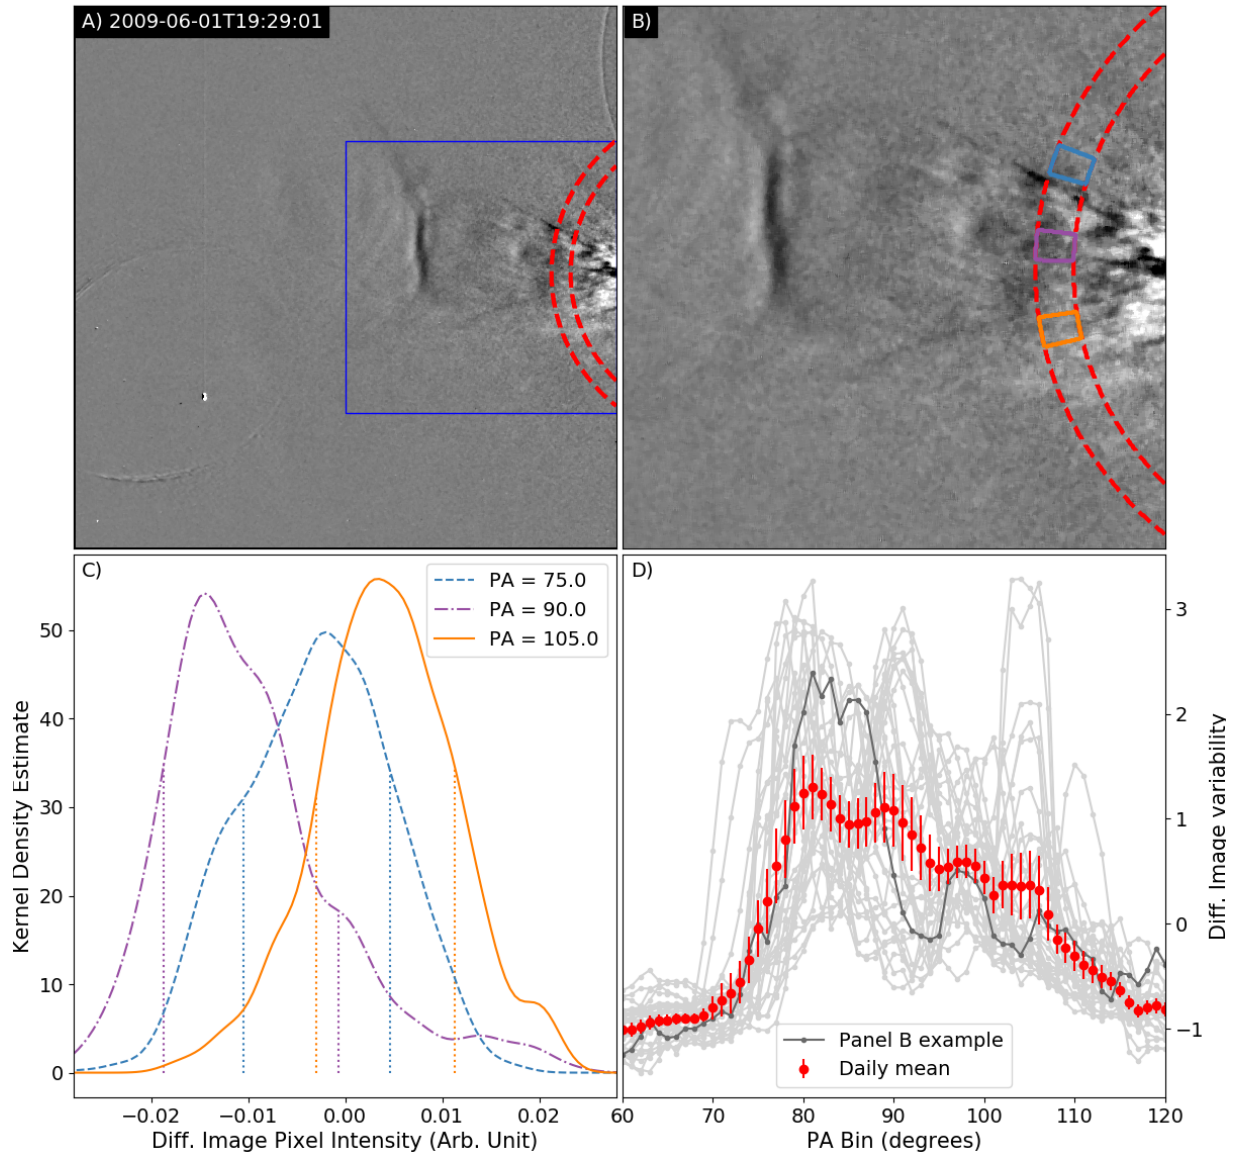

Figure 1. A) A HI1A differenced image from 2009-05-01T19:29. The region enclosed in the blue square is the image segment shown in the expanded view in panel B, while the red-dashed contours show the elongations corresponding to plane-of-sky distances of 20-22.5 solar radii. B) This expanded view of the HI1A differenced image shows more clearly the plane-of-sky region of interest, bounded by the red contours. Within this region, 3 position angle boxes are drawn at ψ of 75°, 90°, and 105° by the blue, purple, and orange lines, respectively. C) Kernel density estimates of the $I(\epsilon, \psi)$ values corresponding to the pixels within the three position angle boxes in panel B. Vertical dashed lines beneath each distribution show the $\pm\gamma(\psi)$ limits around the mean value, demonstrating that $\gamma(\psi)$ is a fair measure of the spread of these distributions. D) The black line shows $\gamma_z(\psi)$ for the HI frame in panel B, while the grey lines show $\gamma_z(\psi)$ for the other HI frames from 2009-05-01. The red points mark $\Gamma(\psi)$ for 2009-05-01, while the uncertainty bars show one standard error of the mean.

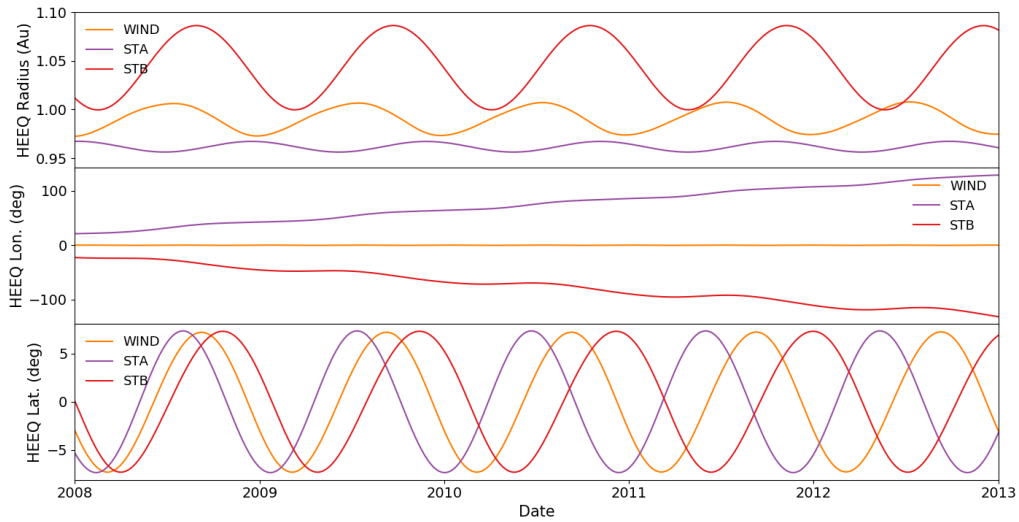

Figure 2. Time series of the Heliocentric Earth Equatorial (HEEQ) coordinates of the WIND, STA and STB spacecraft. The top, middle and bottom spacecraft show the radial, longitudinal and latitudinal coordinates, respectively.

2.4 STEREO-A, STEREO-B, and WIND orbits

Sections 2.1 and 2.2.1 described how STA and STB were in orbits drifting relative to Earth, and that WIND was in a halo orbit around the L1 Lagrange point. Therefore, the relative locations of these three craft are continuously evolving, as described by Figure 2, which shows the Heliocentric Earth Equatorial (HEEQ) coordinates of WIND, STA, and STB, from 2008-01-01 until 2012-12-31. The top, middle and bottom panels presents the HEEQ radius, longitude and latitude respectively. This shows that, for any time over this period, STA, STB, and WIND sample increasingly separate locations in the heliosphere. Consequently, when attempting to link these in-situ solar wind observations with features in the HI remote sensing data, these three craft provide independent data which map to different elements in the full HI data set, and so provide additional confidence that the statistical relationships we demonstrate below are robust.

3 Methods

3.1 Spearman's rank correlation

Spearman's rank correlation is a correlation coefficient that provides a measure of the degree of association between two parameters [Wilks, 1995]. This is a non-parametric statistical measure, as the degree of association is assessed on the ranks of the variables, rather than the actual values. Formally, for N paired observations of two parameters X and Y , Spearman's rank correlation coefficient r_s is computed by first transforming the paired samples X_i and Y_i into their respective ranks Rx_i and Ry_i , and then computing

$$r_s = \frac{\sum_i^N (Rx_i - \overline{Rx})(Ry_i - \overline{Ry})}{\sigma_{Rx}\sigma_{Ry}(N-1)} \quad (3)$$

where \overline{Rx} and σ_{Rx} , and \overline{Ry} and σ_{Ry} , are the means and standard deviations of the ranks Rx and Ry . Consequently, r_s is a measure of how well the relationship between two variables may be modelled by a monotonic relationship. This differs from the more commonly used Pearson's product-moment correlation coefficient, which is a measure of how

well two variables can be modelled with a linear relationship. Furthermore, interpretation of Pearson's correlation is complicated in situations when the paired samples do not form a bi-variate normal distribution. The solar wind plasma properties and statistics computed from the HI images are not normally distributed, and there is no a-priori reason to assume a linear relationship between them, hence using Spearman's rank correlation in this analysis.

Additionally, the statistical significance of r_s can be computed, relative to a null-hypothesis that there is no correlation between the samples [Wilks, 1995]. Such a process can not confirm that a relationship exists between the variables, but it can quantify how unusual it would be to obtain the sample correlation if the true correlation were zero. Here we employ a bootstrap resampling procedure to estimate the distribution of r_s under the null hypothesis that the true correlation is zero. Under such a null hypothesis, the pairing of the samples is irrelevant, and so computing r_s for many random realisations of the paired samples provides an empirical estimate of the distribution of r_s under the null. By comparing the sample r_s to the estimated null distribution, we can assess the likelihood of obtaining the sample r_s due to random sampling of uncorrelated parameters.

3.2 Autocorrelation functions

Here we also compute the autocorrelation function (ACF) of solar wind plasma parameters and statistics derived from the HI images. An ACF is simply the correlation between a parameter and a lagged copy of itself, for a range of different lags. Any measure of correlation can be used to compute an ACF, and here we choose to compute the Spearman ACF.

Similar to computing the statistical significance of r_s for a paired sample of two parameters, the significance of the ACF at any particular lag may also be estimated. This procedure is analogous to the case of a paired sample of two parameters, except that this must be applied at each lag.

4 Results

4.1 ACFs of V and σ_{hi}

Figure 3 shows the time series and ACFs of V for WIND, STA, and STB, respectively. These time series show the same broad features at WIND, STA, and STB, despite sampling increasingly different regions of the heliosphere throughout this period. For example, with increasing longitudinal separation, these monitors will experience different transient structures, and, even in a quiet and steady heliosphere, latitudinal differences mean the monitors still observe different solar wind structure. Panels B1:B3 present the ACFs of these V data for WIND, STA, and STB (black lines). The red dashed lines show the 0.5 and 99.5 percentiles of the null distribution of r_s , estimated from the resampling procedure detailed in section 3.1. Each ACF has clearly defined maxima at lags of approximately 27 and 54 days, corresponding closely with the synodic solar rotation period / Carrington rotation time, as discussed by Owens *et al.* [2013]. The ACF is computed out to a lag of 75 days, and for much of this window the ACF values are larger than would be expected due to random sampling under the null hypothesis of zero correlation. We suggest that, between the maxima, the ACF is larger than expected for zero correlation possibly due to solar cycle scale variations introducing persistence at long timescales. Similar results are obtained for ρ , and T . For conciseness these figures are not included here, but are available in the supplementary information.

Figure 4 shows the time series of HI1A relative variability $\Gamma_{\psi,t}$, over the same time window as the V data in Figure 3. Panel A1 shows the full series of $\Gamma_{\psi,t}$ for all computed position angles between 70° and 105° . Each vertical slice shows one daily mean,

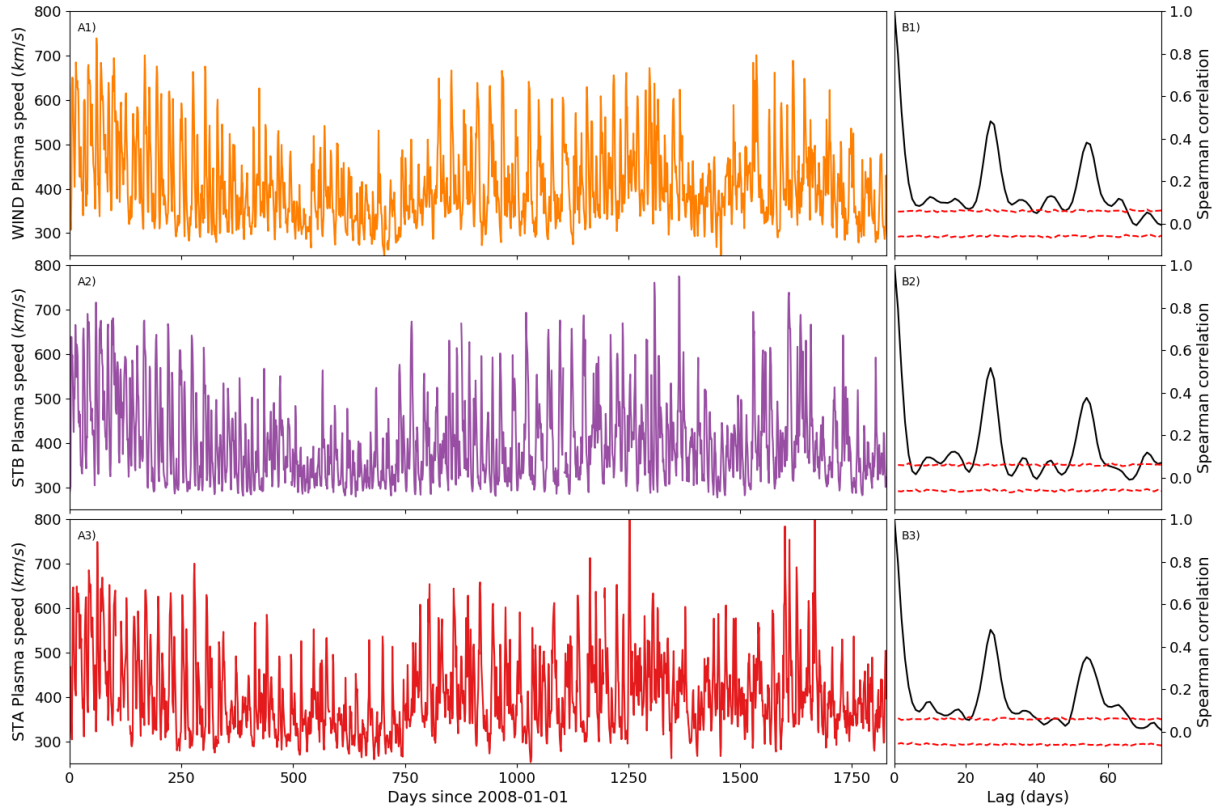

Figure 3. Panels A1:A3 show time series of daily mean solar wind speed estimates from WIND, STA, and STB respectively, for the period of 2008-01-01 until 2012-12-31. Panels B1:B3 show the ACFs (solid black lines) of the daily mean solar wind speed values, for WIND, STA, and STB respectively. The dashed red lines show the 0.5 and 99.5 percentiles of the estimated null distribution of r_s .

337

338

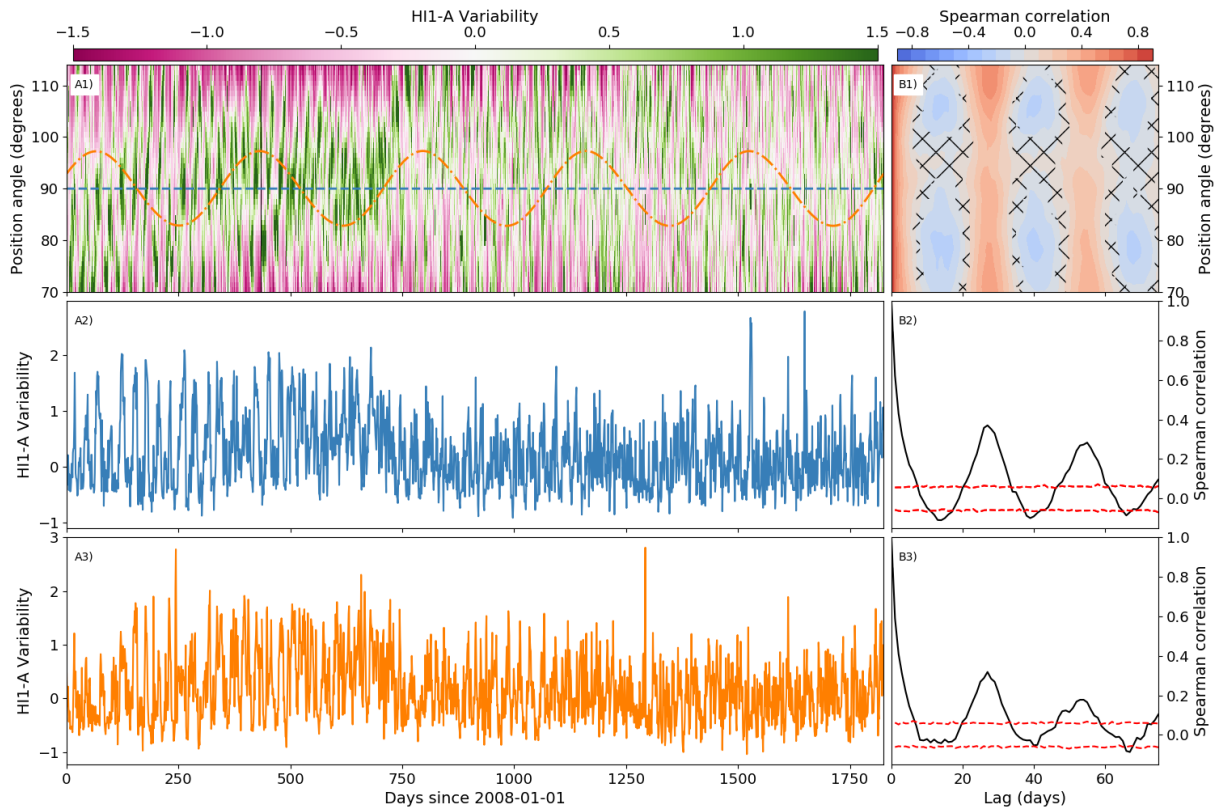

339

with green regions reflecting larger $\Gamma_{\psi,t}$, and pink regions smaller $\Gamma_{\psi,t}$. This shows that, broadly speaking, there is more variability near equatorial position angles (around 90°), and less variability at more polar position angles, similar to that shown in Figure 1 panel D. There are more clearly defined boundaries between more and less variable regions earlier in the time series, which becomes more diffuse and complex after approximately day 750. Nonetheless, the time series in panel A1 is suggestive of periodic structure, which is investigated further in panel B1. The ACF of the $\Gamma_{\psi,t}$ data was computed for each ψ , and these data are presented as a contour of the ACF values as a function of ψ and lag in panel B1. The significance of the ACF was computed using the same resampling procedure, and areas marked with diagonal hatching in the contour plot are within the 99% confidence interval of the null distribution of r_s . At all considered ψ , we observe the same approximately 27 and 54 day peaks in the ACF, similar to the ACFs of V , corresponding to the Carrington rotation time. Panels A2 and B2 present a reduced form of these data, showing only the time series of $\Gamma_{\psi,t}$ corresponding to the equatorial ψ of 90° , as marked by the dashed blue line in panel A1. Finally, panels A3 and B3 present the time series and ACF of $\Gamma_{\psi,t}$ data corresponding to the ψ variation of the WIND spacecraft. This was computed by using nearest-neighbour interpolation to look-up the $\Gamma_{\psi,t}$ values corresponding to the time- ψ variation of WIND, as a synthetic example of how mapping a spacecraft orbit onto the $\Gamma_{\psi,t}$ data might differ from the ACFs observed for fixed ψ considered in rows 1 and 2. In short, no significant change is observed between the ACFs corresponding to the fixed ψ or ψ variation matching WINDs orbit.

Although we are not certain what changes in HI variability, and its latitudinal structure, one possible explanation is the different nature of fast and slow solar wind, and the distribution of their source regions as a function of heliographic latitude. In-situ observations show that the slow solar wind is typically more dense and more variable than fast solar wind, with differing turbulent profiles [Neugebauer and Snyder, 1966; Bruno and Carbone, 2013]. We also note that Ko *et al.* [2018] recently argued that the magnitude of solar wind velocity fluctuations are a good discriminator between fast and slow solar wind, with slow solar wind typically showing smaller velocity fluctuations, although this work did not consider density fluctuations. Furthermore, in-situ and remote observations demonstrate that fast solar wind originates from coronal holes, which tend towards more polar latitudes, particularly at solar cycle minimum [Zirker, 1977; Schwenn, 2007]. Conversely, at solar cycle maximum, slow solar wind is not confined to equatorial regions, and is emitted from a wider range of latitudes. Consequently, we might reasonably expect to observe more differenced image variability along lines of sight containing more slow solar wind that is denser and more variable, and less differenced image variability along lines of sight with more fast wind, which is less dense and less variable. Furthermore, this picture is consistent with the trend shown in Figure 4A1; There is a clearer distinction between variability at high and low latitudes from 2008 - 2010, during the low activity period spanning the solar cycle 23 / 24 transition; As the solar cycle progresses towards the maximum of solar cycle 24 (2014), there is less of a clear distinction between regions of high and low variability as a function of heliographic latitude. On the basis of this interpretation, we tentatively suggest there might be a negative correlation between HI variability and solar wind speed.

4.2 Rolling ACFs of V and σ_{hi}

Of course, simply demonstrating that the ACFs of V for different in-situ monitors and also $\Gamma_{\psi,t}$ are remarkably similar over the period 2008-01-01 to 2012-12-31 is not, in isolation, good evidence that $\Gamma_{\psi,t}$ is a potentially useful tracer of solar wind structure. Another test is to examine how these ACFs evolve over the studied period. Here we do this by computing the ACFs in a rolling window for V_{wnd} , V_{sta} , and V_{stb} , and for traces extracted from $\Gamma_{\psi,t}$ that match the ψ variations of WIND, STA, and STB. We use a rolling window 365 days wide, which is stepped forward in 14 day increments. These parameters were arbitrarily chosen, but the results are not sensitive to modest changes in the window

354 **Figure 4.** Panel A1: Time series of the $\Gamma_{\psi,t}$ data, for all position angles considered. Pink and green regions
 356 show areas of lesser and greater $\Gamma_{\psi,t}$. Panels A2 and A3 present reduced versions of the $\Gamma_{\psi,t}$ data, corre-
 357 sponding to a ψ slice of 90° and the ψ variation of the WIND spacecraft, as marked by the blue dashed line
 358 and orange dash-dot line in panel A1, respectively. Panel B1: A contour plot of the ACFs computed along
 359 each ψ of the $\Gamma_{\psi,t}$ data. Hatched regions highlight areas where the ACFs were within the 99% CI of the null
 distribution of r_S .

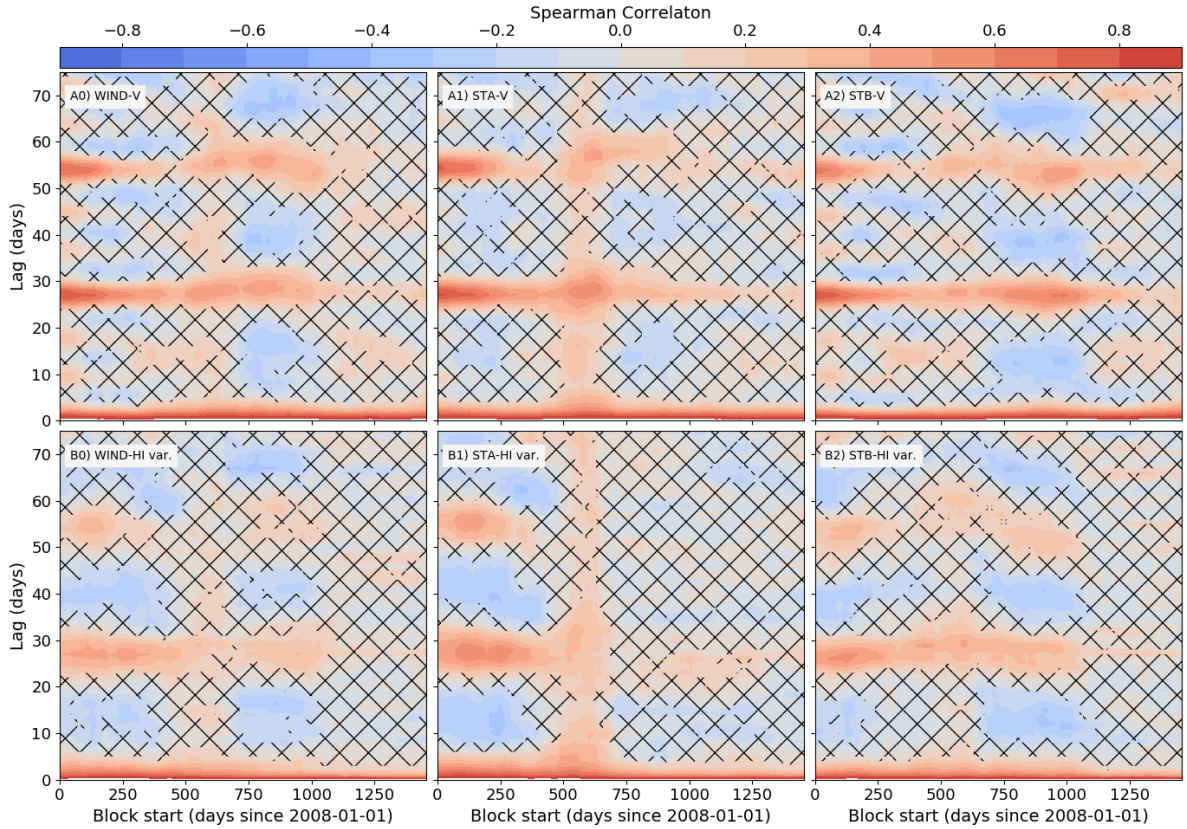

Figure 5. Each panel shows contours of the rolling window ACFs of the V and $\Gamma_{\psi,t}$ data. Each ACF is computed for a 365 day window, stepped forward in 14 day blocks, and in each panel the x-axis shows the block start date, and the y-axis shows the ACF lag. Hatching shows regions where sample ACFs are inside the 99% CI of the null distribution of r_S . Panels A1:A3 show the rolling ACFs for V_{wnd} , V_{sta} and V_{stb} , respectively, while panels B1:B3 show the rolling acfs for $\Gamma_{\psi,t}$ along the ψ traces of the WIND, STA, and STB spacecraft.

width or step size (which was chosen to balance resolution with computational expense). The resulting ACF data are shown in Figure 5, which presents contours of the ACFs as a function of the block start date (x-axis) and lag (y-axis). Panels A0:A2 show the results for V_{wnd} , V_{sta} , and V_{stb} , while panels B0:B2 show the results for the ψ traces extracted from $\Gamma_{\psi,t}$. Throughout, hatching marks areas where the ACF value falls inside the 99% CI limit for the null distribution of r_S .

For each monitor considered, there is clear similarity in the variability of the ACFs between V and the $\Gamma_{\psi,t}$ slices. Considering the very different nature of the in-situ solar wind speed estimates, and the HI differenced image variability data, we regard the similarity of these rolling ACFs as striking. Our tentative interpretation of this is that $\Gamma_{\psi,t}$ is serving as a metric for structure in the ambient solar wind, propagating through the TP of the HI1A FOV.

4.3 Correlation of V and $\Gamma_{\psi,t}$

Given that there appears to be strong correspondence between the ACFs of the in-situ solar wind speed estimates and $\Gamma_{\psi,t}$, we now consider directly the correlation between $\Gamma_{\psi,t}$ and V . However, if slices through $\Gamma_{\psi,t}$ are correlated with V , we should expect there

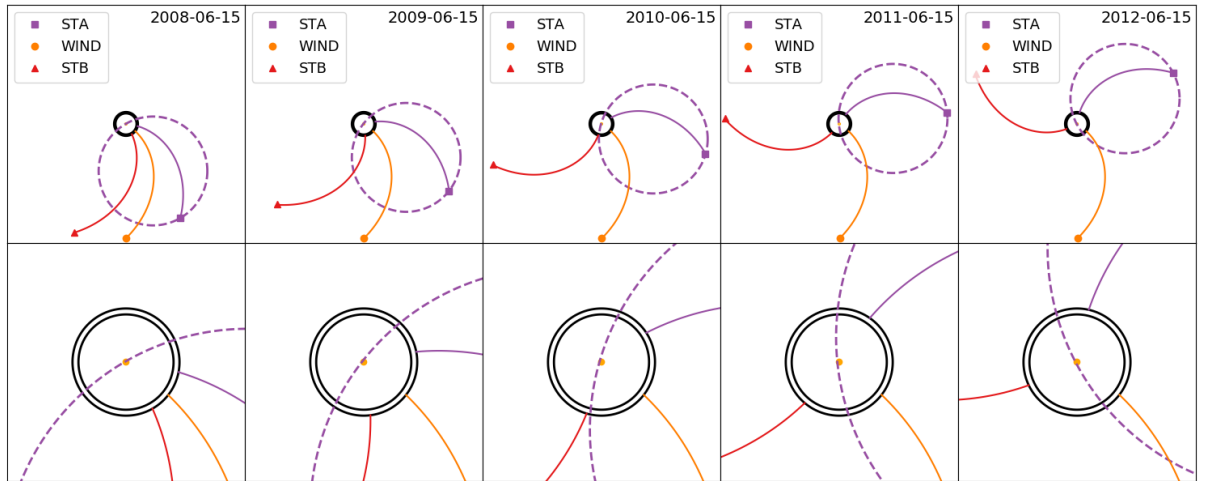

Figure 6. Schematic showing the relative locations of WIND, STA, and STB in the equatorial plane of HEEQ coordinates, for the mid-point times of the calendar years analysed here. Also shown are idealised Parker spiral streamlines connecting each spacecraft to the outer corona. Both rows show the locations of the spacecraft in the Sun's equatorial plane (HEEQ x-y plane), with the bottom row showing an enhanced view of the inner heliosphere. The purple dashed line shows the Thomson sphere of HI1A, while the black circles mark the equatorial intersection of the 20-22.5 R_s plane of sky shell used to compute $\Gamma(\psi, t)$.

to be some temporal lag between these measures, as at any given instant they observe properties of the solar wind which map to different source regions. Consequently, this lag is expected to be a function of the spatial separation of WIND, STA, and STB, recalling that these three pairs of craft have increasing longitudinal separation throughout the study period (Figure 2).

Figure 6 highlights this situation, presenting a schematic which shows the relative locations of WIND, STA, and STB, in the HEEQ equatorial plane, for the mid point times of each calendar year considered here. The top row shows a view of the heliosphere out to the orbits of WIND, STA, and STB, giving the locations of these craft with orange, purple, and red markers. The black circles mark the 20-22.5 solar radii shell used in the HI image analysis, while the solid purple, orange and red lines mark the idealised Parker spiral streamlines for radial wind of 400 km s^{-1} , serving as an approximate indicator of the foot-point of the in-situ monitors. The purple dashed line marks the location of the Thomson sphere for HI1A. The bottom row shows an expanded view of the inner heliosphere, highlighting the relative locations of the intersections between the radial shell, approximate foot-points of the in-situ monitors, and Thomson sphere of HI1A. From this, we form the following hypothesis; the lag between the observed V and $\Gamma(\psi, t)$ values will vary in proportion to the separation between the approximate foot-point longitude, and the longitude of the intersection between the Thomson sphere and radial shell. Consequently, the lag will be approximately constant for STA, due to co-location of HI1 and PLASTIC instruments on STA. Furthermore, as the footpoints of STB and WIND drift closer to and past the Thomson sphere intersection over 2008 - 2012, we expect that initially the lag will be closer to zero for STB than WIND, until eventually WIND is closer and has lags nearer zero. Finally, as STB and WIND drift at approximate 40° and 20° per year relative to STA, we expect the optimal lag for STB to change faster than the optimal lag for WIND.

To investigate this, we split the V series into annual blocks for 2008-2012 (inclusive), and compute the lagged correlation between the V series and the $\psi - t$ trace ex-

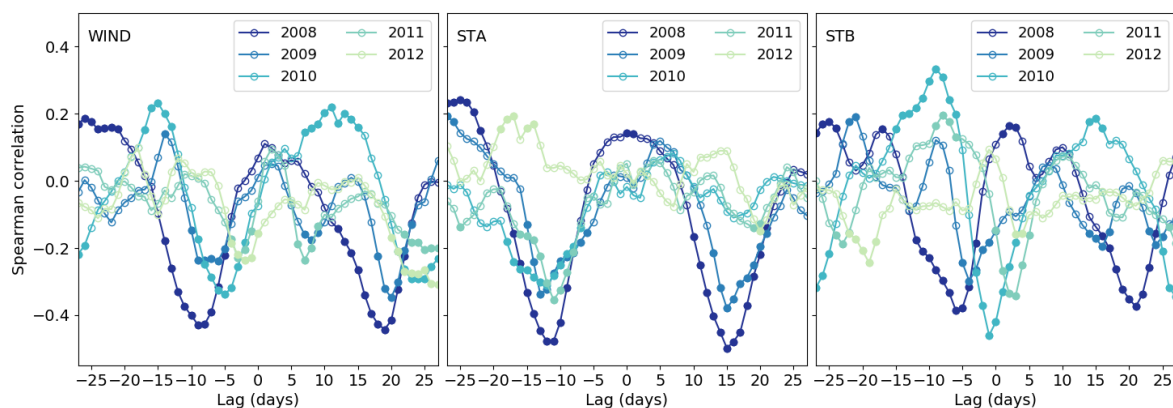

Figure 7. Lagged correlation between $\Gamma(\psi, t)$ and V for WIND, STA and STB. The time series were split into 1 year blocks, and the lagged correlation was computed within each year, for lags between -27 and $+27$ days. Successive years are plotted with lighter colors. Correlations outside of the 99% CI of the null distribution of r_s are marked with a full marker, while those within the 99% CI of the null distribution are hollow.

tracted from $\Gamma(\psi, t)$, for lags between ± 27 days. Note that because of the annual variation in ψ for each craft, the lag is applied to the look-up of the trace from $\Gamma(\psi, t)$; for $V(t, \psi)$, we look-up $\Gamma(\psi, t + l)$, where l is the lag. This simple approach is similar to one used in *Riley and Lionello* [2011], who used simple lagged correlations to relate modelled solar wind speeds at $30 R_s$ and at $1 AU$. Figure 7 presents these lagged correlations for each of WIND, STA and STB, where each year is plotted in an increasingly light color. Filled circular markers highlight correlations which fall outside of the 99% CI of the null distribution of r_s , assessed through resampling tests.

For each of WIND, STA and STB, there are well defined peaks in the lagged correlation. In particular, each craft displays two strong minima in the lagged correlation for most years, excepting only the 2012 period in STA and STB. In each year, these double minima are separated by approximately 27 days. We note this is consistent our interpretation of Figure 4, where we discussed that we might expect there to be a negative correlation between solar wind speed and HI variability.

The results of the lagged correlation are broadly consistent with our hypothesis, as described below. Consider first the lagged correlation of the STA data. The lags of the minima are relatively constant, indicative of the fixed relative locations of the HI1 and PLASTIC instruments on STA. We also note the approximately 3 day asymmetry between the two groups of the minima in STA (at approximately -12 and $+15$ days respectively), which might be explained by the mean solar wind travel time between the source region and STA.

For both STB and WIND, the lags of the minima become more positive throughout 2008-2012. Considering the group of minima at more negative lags for each craft, they are initially closer to zero for STB, and eventually become closer to zero for WIND. This is consistent with the expectations based on the drifting HEEQ longitudes of the approximate footpoints of STB and WIND relative to the TS of STA and radial shell used to compute $\Gamma(\psi, t)$.

Figure 8 quantifies this relationship, plotting the lag of minimum correlation for each year, for WIND, STA, and STB. To compute this we selected the group of minima at more negative lags for WIND and STB, and the group of minima between lags of ± 10 days for STA. The markers show the lag of minimum correlation in years since 2008 (cen-

Gradient	WIND	STA (no outlier)	STB
	1.7 ± 0.2	0.1 ± 0.5	2.5 ± 0.3

Table 1. Gradients (and 2σ errors) of the regression lines shown in Figure 8

493 tred in the middle of the year block), while the solid lines show the linear regressions of
 494 these points, and the dashed lines the 2σ uncertainty on the gradient of the regression
 495 line. The gradients of these regression lines are given in Table 1. For STA, the outlying
 496 point in the last year block (Figure 8) was not included in the regression. These demon-
 497 strate that, as expected, for STA the drift in the lag of the minimum correlation is, within
 498 errors and excluding an outlier, consistent with zero. Furthermore, the drift in the mini-
 499 mum lag for STB is more rapid than for WIND, being approximately 1.5 times the WIND
 500 drift. Naively, we expected the STB drift to be approximately 2 times the WIND drift, and
 501 don't currently understand why it is less than this, but within the uncertainties of this anal-
 502 ysis we consider it broadly consistent with our earlier hypothesis.

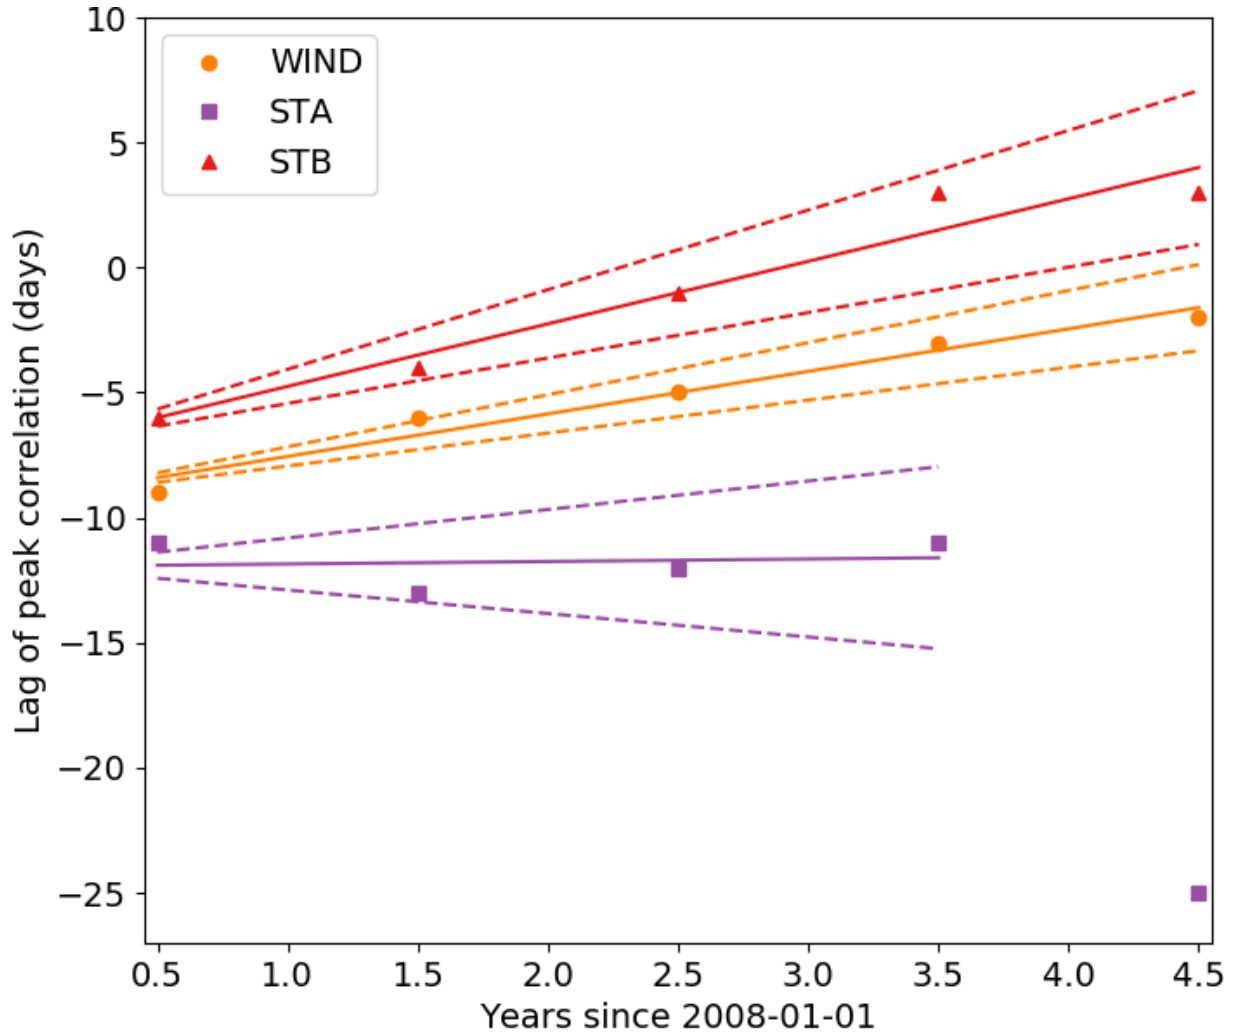

510 5 Conclusions

511 We have demonstrated that, over the period 2008-01-01 to 2012-12-31, variability in
 512 differenced images from HI1A displays Carrington rotation periodicities, with an ACF re-
 513 markably similar to that obtained from in-situ estimates of solar wind speed from WIND,
 514 STA, and STB. Furthermore, considering a sequence of shorter windows in this 5 year pe-
 515 riod, it was shown that the temporal evolution of the ACF was similar for the in-situ solar
 516 wind speed estimates and HI differenced image variability.

517 It is perhaps not a great surprise that we have demonstrated Carrington rotation pe-
 518 riodicities in HI1A differenced images. For example, it is well established that the HI in-
 519 struments can be used to track the “Sheeley blobs” entrained into CIR structures [Rouil-
 520 lard *et al.*, 2008], and subsequent work has revealed that these are observed to have a
 521 quasi-periodic release into the HI FOV, with a typical release timescale of approximately
 522 19hr, across a wide range of heliographic latitudes [Conlon *et al.*, 2015; Sanchez-Diaz
 523 *et al.*, 2016]. CIR structures recur with approximately 27 day periods, and so it is plausi-
 524 ble that measure of differenced image variability we use here, $a\Gamma(\psi, t)$, is acting as a tracer
 525 for such structures. However, these prior works all relied on manual feature tracking in the
 526 HI FOV, to extract the t - ϵ - ψ variation of each blob. We are unaware of any work that has
 527 demonstrated Carrington rotation periodicities in simple statistics computed from the HI
 528 images.

529 Further to this, we have demonstrated a statistically significant correlation between
 530 HI1A differenced image variability and in-situ estimates of solar wind speed from WIND,
 531 STA, and STB. Although it is always wise to be cautious of the results of a correlation
 532 analysis, we consider this a robust result as similar correlations were found for three in-
 533 dependent in-situ monitors that have sampled increasingly separate regions of the helio-
 534 sphere. Finally, there are systematic drifts in the correlation between in-situ solar wind
 535 speed estimates and HI1A differenced image variability which are well explained by the
 536 varying relative locations of the WIND, STA, and STB spacecraft.

537 If, as suggested here, a simple statistical analysis of HI1A images can provide an esti-
 538 mate of near-Sun solar wind speed structure, it increases the likelihood that heliospheric
 539 imaging can provide a valuable external constraint to MHD modelling of the heliospheric
 540 solar wind, through models such as ENLIL, MAS and EUFORIA etc. In particular, we
 541 are interested in investigating how HI data may be used within a data assimilation scheme
 542 for heliospheric modelling, as per Lang *et al.* [2017] and Lang and Owens [2019]. If it
 543 were found that HI observations could be used within a data assimilation scheme for he-

504 **Figure 8.** The lag of the minimum correlation between $\Gamma(\psi, t)$ and V as a function of the mid-point time
 505 of the yearly blocks considered in Figure 7. The lag of minimum correlation steadily increases for STB and
 506 WIND, while is relatively constant for STA, excepting the outlier in the last year block. The solid lines show
 507 the standard least-squares linear regression of each set of points, while the dashed lines give the 2σ errors on
 508 the gradient, the statistics of which are stated in Table 1. For STA, the outlying point in the last year block was
 509 not included in the regression.

544 heliospheric modelling, it would provide a good argument for a heliospheric imager to be
545 included on any future operational space weather monitoring space craft.

546 Having said this, the analysis presented here is clearly exploratory, and it moti-
547 vates a more thorough investigation of the relationship between heliospheric imaging and
548 in-situ solar wind parameters. In our opinion, there are several avenues of investigation
549 that should be prioritised. Firstly, we have used only the standard level 2 science data for
550 HI1A. *DeForest et al.* [2011] presented a method for processing the HI observations which
551 increases the signal to noise ratio relative to standard level 2 data, referred to as L2S im-
552 ages by *DeForest et al.* [2016]. These L2S images may better constrain the relationship
553 between HI1 variability and in-situ plasma observations. Furthermore, a particular limita-
554 tion to our investigation is that we have not explored what scale size features in HI might
555 be best related to in-situ observations. We employed a radial shell in the plane of the sky
556 from $20\text{--}22.5R_s$, position angle bins 5° wide and 1 day means, which means we are look-
557 ing at only one scale of feature. An analysis that considers multiple scale sizes within the
558 HI images would be informative in determining what features are best related to the in-situ
559 plasma observations.

560 Acknowledgments
