## ABSTRACT

22 By comparing a Single Column Model (SCM) with closely related Gen-  
23 eral Circulation Models (GCMs), precipitation changes that can be diagnosed  
24 from local changes in surface temperature ( $T_S$ ) and relative humidity ( $RH_S$ )  
25 are separated from more complex responses. In the SCM set-up, the large-  
26 scale tropical circulation is parametrized to respond to the surface temperature  
27 departure from a prescribed environment, following the Weak Temperature  
28 Gradient (WTG) approximation and using the Damped Gravity Wave (DGW)  
29 parametrization. The SCM is also forced with moisture variations. First, it  
30 is found that most of the present-day mean tropical rainfall and circulation  
31 pattern is associated with  $T_S$  and  $RH_S$  patterns. Climate change experiments  
32 with the SCM are performed, imposing separately surface warming and  $\text{CO}_2$   
33 increase. The rainfall response to future changes in sea surface temperature  
34 patterns and plant physiology are successfully reproduced, suggesting that  
35 these are direct responses to local changes in convective instability. How-  
36 ever, the SCM increases oceanic rainfall too much, and fails to reproduce  
37 the land rainfall decrease, that are both associated with uniform ocean warm-  
38 ing. It is argued that remote atmospheric teleconnections play a crucial role in  
39 both weakening the atmospheric overturning circulation and constraining pre-  
40 cipitation changes. Results suggest that the overturning circulation weakens,  
41 both as a direct local response to increased  $\text{CO}_2$  and in response to energy-  
42 imbalance driven exchanges between ascent and descent regions.

## 43 **1. Introduction**

44     Uncertainty remains in how tropical rainfall will change in the future, particularly at regional  
45 scales. Previous studies have shown that the mean future changes in tropical rainfall mainly consist  
46 in shifts, which over the oceans are mainly driven by changes in the mean Sea Surface Temperature  
47 (SST) pattern, following the so-called warmer-get-wetter mechanism (Xie et al. 2010; Ma and Xie  
48 2013; Chadwick et al. 2014; Kent et al. 2015). However, rainfall changes over land seem to be  
49 driven by more complex combinations of different aspects of the CO<sub>2</sub> forcing, including changes  
50 in the plant physiology, in the atmospheric radiative cooling or in the mean ocean warming (e.g.  
51 Betts et al. 2004; Giannini 2010; Cao et al. 2012; Chadwick et al. 2017). Understanding tropical  
52 rainfall changes under global warming would help to improve future projections that still exhibit  
53 strong disagreement and better inform climate adaptation policy (Knutti and Sedlek 2013; Collins  
54 et al. 2013; Shepherd 2014; Kent et al. 2015; Oueslati et al. 2016; Long et al. 2016).

55     Based on the observation that horizontal gradients of free-tropospheric temperatures are weak  
56 in the Tropics, the so-called Weak Temperature Gradient (WTG) approximation suggests that con-  
57 vective instability is largely driven by spatial variations in surface temperature and moisture (Sobel  
58 and Bretherton 2000; Sobel et al. 2001). The influence of free-tropospheric moisture gradients on  
59 precipitation patterns is not ruled out by the WTG approximation.

60     Based on this theory, Lambert et al. (2017) and Todd et al. (2018) have diagnosed tropical  
61 rainfall patterns and shifts from two surface observable variables, surface Temperature ( $T_S$ ) and  
62 near-surface Relative Humidity ( $RH_S$ ), with the idea that precipitation falls in the highest  $T_S$  and  
63  $RH_S$  regions. This view is based on the argument (from convective quasi-equilibrium and WTG  
64 approximation) that tropical precipitation is a function of  $T_S$  and  $RH_S$  and that rainfall shifts can  
65 be diagnosed from the combination of  $T_S$  shifts and  $RH_S$  shifts.

66 The general aim of this study is to test how much of the pattern of mean tropical precipitation  
67 and its response to climate change can be simulated from  $T_S$  and  $RH_S$  patterns using a Single  
68 Column Model (SCM) under the WTG approximation. This study first investigates how much of  
69 the present-day annual-mean tropical rainfall pattern simulated by a General Circulation Model  
70 (GCM) can be reproduced by reconstructing only three elements: 1) the environment provided  
71 by the tropical mean-state, 2) the  $T_S$  tropical pattern, 3) the  $RH_S$  tropical pattern. Simulating a  
72 single atmospheric column, embedded in a pre-determined environment, allows us to reconstruct  
73 those three elements since the only information needed is: 1) the moisture and temperature pro-  
74 files that describe the tropical environment, 2) the local  $T_S$  anomaly at each location (departure  
75 from the environment), 3) the local  $RH_S$  at each location. We use an SCM modified to imple-  
76 ment the WTG approximation, so that precipitation in the column responds to the  $T_S$  anomaly via  
77 the parametrization of the large-scale circulation. The latter is done using the so-called Damped  
78 Gravity Wave (DGW) parametrization method (Bergman and Sardeshmukh 2004; Kuang 2008,  
79 2011; Wang et al. 2013) and has been implemented following Daleu et al. (2015). Similar set-ups  
80 have been used in many studies (e.g. Sobel and Bretherton 2000; Chiang and Sobel 2002; Sobel  
81 et al. 2007; Sobel and Bellon 2009; Zhu and Sobel 2012). In addition, we implement the variation  
82 of moisture in the column in order to represent the precipitation response to  $RH_S$ . The SCM is  
83 run multiple times to reconstruct the tropical  $T_S$  and  $RH_S$  patterns from the corresponding parent  
84 GCM. The rainfall pattern reproduced from this reconstruction is then compared with the GCM.  
85 The experimental set-up is described in detail in Section 2.

86 In the second part of the study, increased atmospheric  $\text{CO}_2$  and uniform surface warming are  
87 independently applied to the SCM in order to investigate how much of the rainfall response can  
88 be reproduced by reconstructing: 1) the change in the tropical mean-state environment, 2) the  
89 change in the  $T_S$  tropical pattern, 3) the change in the  $RH_S$  tropical pattern. Those three compo-

90 nents are reconstructed for different aspects of CO<sub>2</sub> forcing, such as uniform ocean warming, SST  
91 pattern change or direct radiative effect of increased atmospheric CO<sub>2</sub>. They are taken from GCM  
92 atmosphere-only experiments in which these boundary conditions have been applied. Rainfall  
93 changes reproduced from these reconstructions in the SCM are then compared to the correspond-  
94 ing GCM experiment.

95 In addition to rainfall, we also investigate changes in convective mass fluxes which can be used  
96 as a proxy for the intensity of the atmospheric circulation. Precipitation can be approximated as  
97 the product of near-surface specific humidity and vertically integrated convective mass flux. In  
98 a warmer and wetter climate, rainfall can increase even as convective mass flux decreases (Held  
99 and Soden 2006). Convective mass flux is expected to weaken in response to climate change,  
100 which has been attributed to the reduction of radiative cooling, or the enhanced warming of the  
101 subtropics, or the increase in dry static stability as a response to surface warming (e.g. Knutson  
102 and Manabe 1995; Held and Soden 2006; Vecchi and Soden 2007; Ma et al. 2012; Chadwick et al.  
103 2013; Bony et al. 2013; He et al. 2014; He and Soden 2015). In order to test these mechanisms in  
104 the SCM, we use a more direct approach where we look at the direct response of the column to the  
105 forcing, without reconstructing  $RH_S$  patterns changes from the GCM. This way, we use the SCM  
106 to further understand whether the tropical circulation weakening is a direct or indirect, uniform or  
107 non-uniform response to increased atmospheric CO<sub>2</sub>. The weakening of the tropical circulation  
108 further affects the rainfall changes, which are also investigated.

## 109 **2. SCM description and set-up**

110 The SCM uses the Met Office Unified Model Global Atmosphere version 7.1 in one dimension,  
111 which is also used in three dimensions in the atmosphere-only GCM HadGEM3 (Walters et al.  
112 2019). The surface is prescribed, with no ocean or land-surface model. The SCM has interac-

113 tive radiation and solar diurnal cycle. There is no surface temperature variability applied on any  
114 timescale.

115 *a. Parametrization of the large-scale circulation in the SCM*

116 Conceptually, the SCM represents two atmospheric domains: the simulated column and a pre-  
117 scribed environment that typically represents the tropical mean. The environment is defined by  
118 reference vertical profiles of potential temperature  $\theta$  and specific humidity  $q$ . In order to de-  
119 termine these profiles, the SCM is first run in Radiative-Convective Equilibrium (RCE) mode:  
120 vertical velocity is set to zero so that convective heating balances radiative cooling. Surface tem-  
121 perature is prescribed and represents the tropical average SST. Reference profiles of  $\theta$  and  $q$  are  
122 determined from the equilibrated state of the RCE run. They will constitute the environment and  
123 initial state for DGW-parametrized SCM simulations, described below, with their mathematical  
124 framework detailed in appendix A.

125 In the single column simulated using the DGW parametrization, the prescribed surface tempera-  
126 ture affects the column stability (compared to the initial state/environment), which in turns affects  
127 convection and convective heating, warming or cooling the column. The column is also warmed  
128 or cooled by changes in the sensible heat flux and in water vapour and clouds which then feed  
129 back on the column radiative heating. The vertical velocity  $w'$ , that is the marker of the large-scale  
130 circulation in the column, is parametrized to respond to the column temperature anomaly. The  
131 subsequent vertical advection of  $\theta$  relaxes the simulated  $\theta$  profile towards the reference  $\theta$  profile,  
132 maintaining approximate uniformity with the environment, as dictated by the WTG approxima-  
133 tion (see schematic Fig. 1). Together with the subsequent vertical advection of  $q$ , it further affects  
134 rainfall.

135 Another method commonly used is the WTG parametrization (Sobel and Bretherton 2000; Sobel  
136 et al. 2001), that is only used here in the Supplementary Material. Note that both the DGW and  
137 the WTG parametrization methods follow the WTG approximation. The DGW parametrization  
138 of  $w'$ , unlike the WTG parametrization, takes place in the whole column, including the boundary  
139 layer, without linear interpolation.

140 This SCM set-up represents the local effect of  $T_S$  patterns on convective instability and thus free-  
141 tropospheric latent heating, which then drives low-level convergence (represented by the vertical  
142 velocity in the SCM) and convection. On the other hand, our SCM set-up is not representative of  
143 the Lindzen and Nigam (1987) model, which describes the more direct effect of sharp  $T_S$  gradients  
144 on low-level convergence via their influence on boundary layer pressure gradients. The SCM  
145 parametrization represents the effect of the  $T_S$  anomaly regarding the tropical average, but is not  
146 able to simulate sharp  $T_S$  gradients.

147 Horizontal advection of moisture between the environment and the simulated domain is mod-  
148 elled using simultaneously two different schemes that represent two different processes: (1) the  
149 horizontal advection by the locally parametrized mean divergent circulation (lateral drawing), (2)  
150 the horizontal advection by the mean rotational flow and transient eddies in the form of a relaxation  
151 of the domain  $q$  profile towards the environmental  $q$  profile (moisture relaxation). The time-scale  
152 used for this relaxation is 1 day, which would be typical of horizontal moisture mixing between the  
153 simulated domain and a surrounding environment that is far enough away to be independent of the  
154 former. More details and mathematical formulation of the DGW parametrization and horizontal  
155 advection of moisture are given in appendix A.

156 *b. Varying moisture in the SCM*

157 During a further stage of this study, in order to include variations of moisture and to be able to  
158 produce various values of  $RH_S$  (particularly low values found over land), we add to this set-up a  
159 scaling of both surface evaporation (with a coefficient  $\beta$ ) and environmental  $q$  profile. The envi-  
160 ronmental  $q$  profile is scaled with the same coefficient throughout the whole column. We use a  
161 range of combinations of those two scaling coefficients for each surface temperature. This allows  
162 us to vary moisture in the column, which also affects precipitation. It also allows us to have a better  
163 representation of the different tropical regions since there is no weak moisture gradient principle  
164 in the tropics. The  $\beta$  and  $q$  profile scaling coefficients are determined by spatial clustering anal-  
165 yses (see section 1 of Supplementary material). Following these analyses, surface evaporation is  
166 varied using 5 coefficients that represent: (1) the ocean ( $\beta=1$ ), (2) rainforests ( $\beta=0.75$ ), (3) a 20%  
167 reduction of the evaporation over rainforests as is expected in response to  $4\times\text{CO}_2$  increase (our  
168 vegetation-only forcing component with prescribed land gives a 17% reduction over rainforests  
169 latitudes over land) ( $\beta=0.6$ ), (4) wet regions ( $\beta=0.5$ ), (5) semi-arid regions ( $\beta=0.2$ ). The environ-  
170 mental  $q$  profile is varied using 7 coefficients that represent: heavy rainfall convergence zones and  
171 rainforests (scaling coefficient = 1 and 1.1), north and south subtropics (0.8 and 0.7), north and  
172 south equatorial bands (1 and 0.9), deserts (0.4) and the Amazon during wet season (1.25).

173 *c. Experimental design*

174 First, the SCM is run in RCE mode in order to determine the environment. Atmospheric  $\text{CO}_2$   
175 concentrations are set to mid-1970s values. The run is performed for 100 days at  $T_s^{RCE} = 300$  K,  
176 which is approximately the mean SST over the tropics (20N-20S). Reference  $\theta$  and  $q$  profiles are  
177 determined from the time-mean over the last 40 days of the RCE run. These profiles are then used  
178 as initial state and environment in the SCM runs under the DGW parametrization.

179 In the first stage of this study, the SCM is run 13 times under the DGW parametrization, with  
180 the surface temperature varying from 297.5 to 303.5 K, in increments of 0.5 K ( $\beta$  and the environ-  
181 mental  $q$  profile scaling coefficients are both set to 1). This set of experiments will be referred to  
182 as SCM\_CTRL\_ $T_S$ -only.

183 During a further stage of this study, the SCM is run multiple times with many possible com-  
184 binations of  $T_S$ ,  $\beta$  and environmental  $q$  profile scaling. In total a set of 455 ( $13 T_S \times 5 \beta \times 7 q$   
185 scalings) SCM experiments are run to cover enough possibilities of  $T_S$ ,  $RH_S$  and rainfall conditions  
186 in the column in order to reproduce rainfall patterns. We will refer to this set of experiments as  
187 SCM\_CTRL.

188 In the last stage of this study, the set of 455 SCM experiments is replicated twice with two  
189 different perturbations. The control set of experiments mentioned above (SCM\_CTRL) serves as  
190 the reference. A first set of perturbed experiments is performed with warmer mean conditions  
191 corresponding to a uniform warming of the surface by 4 K (SCM\_4K). For this set of experiments,  
192 the SCM is first run in RCE mode at  $T_s^{RCE} = 304$  K. Again, this run is performed for 100 days  
193 and the new reference  $\theta$  and  $q$  profiles are determined from the time-mean over the last 40 days.  
194 These new profiles are then used as initial state and environment to perform a new set of runs  
195 under the DGW parametrization: the SCM is run again 455 times, varying  $T_S$  from 301.5 to  
196 307.5 K every 0.5 K, and varying moisture using the same  $\beta$  and  $q$  profile scaling coefficients as in  
197 SCM\_CTRL. A second set of perturbed experiments is performed with increased atmospheric CO<sub>2</sub>  
198 corresponding to the  $4 \times \text{CO}_2$  forcing (SCM\_4xCO<sub>2</sub>). For this set of experiments, the SCM is first  
199 run in RCE mode again at  $T_s^{RCE} = 300$  K as in SCM\_CTRL, but with atmospheric CO<sub>2</sub> multiplied  
200 by 4. As before, the run is performed for 100 days, the new reference profiles are determined from  
201 the time-mean over the last 40 days and then used as initial state and environment to perform a

202 new set of runs under the DGW parametrization: the SCM is run again 455 times, varying  $T_S$ ,  $\beta$   
203 and the  $q$  profile scaling as in SCM\_CTRL but with 4 times more CO<sub>2</sub> in the atmospheric column.

### 204 **3. GCM experiments**

205 Different experiments from different GCMs are compared with the SCM results. They are  
206 all described in Table 1. The most relevant comparison is with the atmosphere-only experiment  
207 AMIP (Atmospheric Modelling Intercomparison Project) performed with the SCM’s parent GCM  
208 HadGEM3 (Walters et al. 2019). We consider 20 years of this experiment from 1989 to 2008 and  
209 refer to it as HG3-AMIP. In HG3-AMIP, prescribed SST is taken from observations.

210 In order to investigate the response to the  $4\times\text{CO}_2$  forcing, we compare the pre-industrial (pi-  
211 Control) and abrupt $4\times\text{CO}_2$  simulations performed with the previous version of the Met Office  
212 Unified Model HadGEM2-ES (Martin et al. 2011). In order to decompose the  $4\times\text{CO}_2$  forcing,  
213 we use atmosphere-only experiments, each perturbed with one isolated component of the forcing  
214 (Table 1). Some of them have been performed with HadGEM2-ES and are described in more  
215 detail in Chadwick et al. (2017) (piSST, p4KSST, a4SST). At the time of writing, none of these  
216 experiments have been performed with HadGEM3 (the SCM’s parent GCM); HadGEM2-ES was  
217 then most likely the closest model to be compared to the SCM. The other atmosphere-only experi-  
218 ments used in this study have prescribed land in addition to prescribed ocean. They have only been  
219 performed with ACCESS1.0 (Bi et al. 2013; Ackerley and Dommenges 2016) and are described  
220 in more detail in Ackerley et al. (2018). ACCESS1.0 and HadGEM2-ES are very similar models  
221 sharing the same configurations of their land-surface and atmospheric components (including con-  
222 vection scheme). Using these “prescribed-land” experiments allows us to decompose the  $4\times\text{CO}_2$   
223 forcing more, since land-surface changes are separated from ocean-surface changes.

224 For all these GCM experiments, the last 30 years are considered. The different components  
225 of the  $4\times\text{CO}_2$  forcing built from combinations of these experiments are defined in Table 2. The  
226 Vegetation-only forcing with prescribed land shows the effect of the plant physiological response  
227 to  $4\times\text{CO}_2$  with prescribed surface temperature over land and ocean. The  $4\times\text{CO}_2$  radiative-only  
228 forcing with prescribed land shows the  $4\times\text{CO}_2$  radiative-only effect (no plant physiology change)  
229 with prescribed surface temperature over land and ocean. Other definitions given in Table 2 are  
230 self-explanatory.

## 231 4. Present-day climate

### 232 *a. Reproduction from surface temperature pattern only*

233 In this part we analyze `SCM_CTRL_T5-only`, where only the surface temperature varies (mois-  
234 ture can vary but evaporation and environmental  $q$  profile scalings are set to 1). This set-up gives  
235 the expected rainfall response to the large-scale circulation induced by surface temperature pat-  
236 terns, under the WTG approximation.

237 `SCM_CTRL_T5-only` precipitation results are shown in Fig. 2a for each surface temperature, and  
238 compared with the HG3-AMIP distribution of precipitation over the ocean, for each corresponding  
239 SST bin. The qualitative relationship between SST and precipitation is fairly well reproduced in  
240 the SCM, but the SCM precipitation is too sensitive to the surface temperature compared with  
241 the GCM. This is associated with an overestimation of the sensitivity of the parametrized vertical  
242 velocity  $w'$  to the surface temperature (Fig. 2b).

243 There are many possible reasons for the SCM not to perfectly reproduce the GCM rainfall. Our  
244 SCM set-up is an idealized model, based on an approximation and with simplified representation  
245 of moisture advection. Besides, the WTG approximation is not always accurate, as the free tropo-

246 spheric temperature is not perfectly uniform across the tropics, particularly outside the equatorial  
247 band (10N-10S) and over land regions outside the equatorial band (Todd et al. 2018). On the other  
248 hand, its accuracy over land regions within the equatorial band has been shown for the Amazon  
249 (Anber et al. 2015). Our SCM set-up is also not meant to capture all the mechanisms that exist  
250 in the GCM; only the effect of  $T_S$  patterns on the large-scale circulation via convective instability  
251 and free-tropospheric heating patterns. However, the most likely reason for the over-sensitivity of  
252  $w'$  and precipitation to the surface temperature is the relative isolation and lack of variability of  
253 the simulated single column. In the GCM, each column is affected by transients, weather systems,  
254 disturbances from nearby columns, that are lacking in the SCM. As it is not disturbed, the vertical  
255 velocity in the single column is relatively free to grow or decline, as a consequence of positive  
256 feedbacks detailed in Supplementary section 2. As a result, the single column reaches a steady  
257 state after a few days, that tends to be either too wet or too dry, even though horizontal mixing of  
258 moisture prevents it from getting excessive (see Supp. sec. 2).

259 Fig. 3b shows SCM\_CTRL\_ $T_S$ -only precipitation results on a map, projecting it on HG3-AMIP  
260 surface temperatures (see Methods). Over the ocean, the precipitation pattern is sensible (corre-  
261 lation over the ocean: 0.7; correlation including land: 0.42). Not surprisingly, it closely follows  
262 the SST pattern (not shown), raining over warm regions. As found in other studies, tropical an-  
263 nual mean rainfall can be fairly sensibly reproduced by an SCM under the WTG approximation  
264 (Sobel and Bretherton 2000; Zhu and Sobel 2012). Over land, precipitation is generally underes-  
265 timated, as a result of land regions being relatively cold compared to the tropical average; except  
266 over the Sahel, northern Australia and India, which are the hottest regions of the tropics and where  
267 precipitation is overestimated.

268 As mentioned before, this SCM set-up represents the effect of  $T_S$  patterns on the large-scale cir-  
269 culation via convective instability and free-tropospheric heating patterns. While this drives most of

270 the low-level wind convergence in the tropics, other mechanisms have been suggested to dominate  
271 in some particular regions, such as regions of strong meridional SST gradients near the equator,  
272 and on the flanks of the oceanic Inter-Tropical Convergence Zone (ITCZ) (Chiang et al. 2001;  
273 Diakhaté et al. 2018). In particular, in the central-eastern Pacific, boundary-layer pressure gradi-  
274 ents driven by the strong meridional SST gradients create low-level wind convergence that forces  
275 convection, rather than being a consequence of it (Lindzen and Nigam 1987; Back and Bretherton  
276 2009). Our SCM set-up does not capture this influence of  $T_S$  gradients on the large-scale circula-  
277 tion via boundary-layer pressure gradients. This could explain some of the differences between the  
278 GCM and the SCM, such as the too-weak and too-wide ITCZ produced by SCM\_CTRL\_ $T_S$ -only  
279 in the north-east Pacific (Fig. 3b), and thus support the idea that the effect of  $T_S$  gradients plays a  
280 key role in this region.

281 Figure 4a confirms the good correspondence between the SCM and the GCM precipitation over  
282 the ocean, as shown by the linear regression of one on another, although the SCM tends to gener-  
283 ally overestimate rainfall. In particular, over some oceanic grid-points (blue dots), the annual-mean  
284 precipitation is high in the SCM but low in the GCM, which corresponds to SCM overestimations  
285 at high SSTs on Fig. 2a. Figure 4a also confirms the lack of correspondence over land, with the  
286 SCM raining too much in GCM dry regions, and not enough in GCM rainy regions (given the poor  
287 correlation over land, no linear regression is shown).

288 In the real world, precipitation and SST patterns do not exactly match. One thing in particu-  
289 lar that SCM\_CTRL\_ $T_S$ -only is missing is the spatial variation of near-surface and atmospheric  
290 moisture. Only one moisture profile was used to define the environment in SCM\_CTRL\_ $T_S$ -only,  
291 while moisture is not uniform across the tropics. Variations of moisture are especially an issue for  
292 representing relatively cold but wet land regions such as rainforests, or hot but dry land regions

293 such as deserts. In the next section and the rest of this study, the column moisture will be varied  
294 (in addition to surface temperature), using SCM\_CTRL, to address these issues.

295 *b. Reproduction from surface temperature and relative humidity patterns*

296 From now on we analyze the SCM\_CTRL set of experiments (see section 2.c), where not only  
297 the surface temperature varies but also moisture, through variations of evaporation and environ-  
298 mental  $q$  profile scalings. Figure 3c shows SCM\_CTRL precipitation results on a map, projecting  
299 it on HG3-AMIP  $T_S$  and  $RH_S$  (see Methods). Considering moisture variation clearly improves the  
300 projected rainfall pattern (higher correlation with HG3-AMIP: 0.8 over the ocean and 0.71 includ-  
301 ing land). Over land, varying moisture now allows the representation of relatively cold and wet  
302 regions like rainforests and hot, dry regions like deserts. In the GCM,  $RH_S$  affects precipitation,  
303 but precipitation also feeds back on  $RH_S$ , so the causality between moisture and rainfall patterns  
304 is unclear. In the SCM, the causality is clearer, even though  $RH_S$  variations are not directly pre-  
305 scribed (but induced by variations in the moisture coefficients), because precipitation has very  
306 limited ways of feeding back on to  $RH_S$ .

307 But what is the SCM not able to capture? Figure 3d highlights differences with HG3-AMIP  
308 precipitation pattern. The sensitivity of precipitation to the surface temperature remains overesti-  
309 mated in the SCM. This is consistent with rainfall over the ocean being too extended spatially and  
310 generally too strong, while regions with low rain rates are generally too dry. This is also consistent  
311 with land regions remaining too dry, except for some rainforests. It remains unclear whether it  
312 is due to the SCM parametrization or whether it has a physical explanation such as rainfall being  
313 driven by other factors than local surface temperature and humidity. Over land, low thermal iner-  
314 tia, consequently strong diurnal cycle, as well as orography or soil moisture play a large role in  
315 circulation and convective systems, none of which are directly represented in the SCM. For exam-

316 ple, the mean precipitation over land partly results from the diurnal cycle of surface temperature,  
317 which may be very different from the precipitation resulting from the mean surface temperature.  
318 Another thing the SCM does not reproduce is the fact that convection over coastal land drives low-  
319 level mass divergence over nearby coastal ocean, forcing subsidence and advective drying there,  
320 which are not well captured by  $T_S$  and moisture patterns. Over the Maritime continent for exam-  
321 ple, even though considering moisture heterogeneity and transport allows a better representation  
322 of rainfall, the SCM still overestimates oceanic rainfall near the coasts. It is generally the case for  
323 African and Asian tropical coasts as well.

324 Figure 4b confirms that the correspondence between the SCM and the GCM precipitation, over  
325 both ocean and land, is substantially improved by considering moisture variations. Despite this  
326 strong improvement, the SCM still tends to be either too wet or too dry over land, exhibiting two  
327 populations of grid-points in GCM rainy regions: one where the SCM remains dry and another one  
328 where the SCM overestimates rainfall. Given the existence of these two populations, regressing  
329 linearly the SCM rainfall on the GCM rainfall over land would not be sensible. Overall, the  
330 SCM still overestimates rainfall over both land and ocean, as further confirmed by the 20N-20S  
331 tropically-averaged annual-mean rainfall, which is 4.84 mm/day in the SCM against 4.34 mm/day  
332 in the GCM.

## 333 **5. Perturbed climate experiments**

334 In the GCM, we choose to decompose the  $4\times\text{CO}_2$  forcing into: (1) land warming due to the  
335 plant physiological response to  $4\times\text{CO}_2$ , (2) land warming due to the  $4\times\text{CO}_2$  radiative-only effect,  
336 (3) effect of the plant physiological response to  $4\times\text{CO}_2$  with prescribed  $T_S$  over land and ocean,  
337 (4) change in the SST pattern, (5)  $4\times\text{CO}_2$  radiative-only effect (no plant physiology) with pre-  
338 scribed  $T_S$  over land and ocean, (6) uniform + 4 K ocean warming. The first three correspond to

339 perturbations in the land surface. The last two correspond to uniform perturbations that strongly  
340 affect the atmospheric budget. We use GCM experiments described in section 3 that isolate those  
341 different components of the  $4\times\text{CO}_2$  forcing. Figure 5a shows the full annual-mean precipitation  
342 response to the  $4\times\text{CO}_2$  forcing, as given by abrupt $4\times\text{CO}_2$ , and Fig. 5b shows the sum of the six  
343 components described above. Fig. 5a and Fig. 5b patterns and magnitudes are consistent (correla-  
344 tion: 0.78), suggesting that those six components add up nearly linearly and that looking at each  
345 one separately can help us to understand the full response.

346 In order to reproduce each forcing component with the SCM, we use the two sets of SCM  
347 experiments perturbed with surface warming (SCM\_4K) and  $4\times\text{CO}_2$  (SCM\_4xCO2) described in  
348 section 2.c. Note that in these cases, the SCM results are compared with experiments performed  
349 with HadGEM2-ES and ACCESS1.0, which use different physical schemes than HadGEM3 (the  
350 SCM's parent GCM). At the time of this study, these experiments have not been performed with  
351 HadGEM3. Therefore, it is worth keeping in mind that this could cause differences between  
352 the GCM experiments and the SCM results. However, we believe this is unlikely to cause major  
353 differences, because SCM\_CTRL projects very well on both piSST (HadGEM2-ES), with a pattern  
354 correlation of 0.68, and AMIP\_PL (ACCESS1.0), with a pattern correlation of 0.73 (when applying  
355 the same method as in section 4.b and Fig. 3c; not shown)

#### 356 *a. Perturbed land surface*

357 Figure 6 shows annual-mean precipitation changes associated with different forcing compo-  
358 nents, as simulated by the GCM (top of each panel) and reproduced by the SCM (bottom of each  
359 panel). Plant transpiration weakens in response to increased atmospheric  $\text{CO}_2$ , reducing evapo-  
360 transpiration and warming the land surface by reducing its cooling capacity (Sellers et al. 1996;  
361 Cox et al. 1999; Dong et al. 2009). Land warming induced by this vegetation forcing, when iso-

362 lated, results in a general rainfall increase over land (Fig. 6a). When land warming is induced  
363 by the direct radiative effect of increased atmospheric CO<sub>2</sub>, the response is similar (Fig. 6c) al-  
364 though with a smaller magnitude, as the magnitude of land warming is also smaller (land warms  
365 by 0.74°C on average when induced by vegetation and by 0.38°C when induced by the radiative  
366 CO<sub>2</sub> effect). In both cases, the SCM captures the general rainfall increase over land (Fig. 6b,d),  
367 confirming that land warming brings more rainfall over land.

368 In the case of the vegetation-induced land warming, the SCM reproduces the right magnitudes  
369 of rainfall increases (Fig. 6b), despite the strong sensitivity of its precipitation to surface temper-  
370 atures (shown in the previous section). This is because we take into account  $RH_S$  variations, that  
371 we reconstruct in the SCM through variations of evaporation and environmental moisture profile  
372 (affecting horizontal moisture advection). Land warming is generally associated with reduced  $RH_S$   
373 over land (Joshi et al. 2008; O’Gorman and Muller 2010; Simmons et al. 2010; Chadwick et al.  
374 2016; Byrne and O’Gorman 2016), as confirmed by Fig. S8g, making the SCM able to capture  
375 land rainfall increases with the right magnitudes. Land warming induced by vegetation also cre-  
376 ates a drying patch over the eastern Amazon (Fig. 6a) which is captured by the SCM (Fig. 6b)  
377 thanks to the associated  $RH_S$  reduction (Fig. S8g). The causality between reduced rainfall and  
378 reduced  $RH_S$  remains unclear. There are a few other spots of land rainfall decrease (northeastern  
379 Brasil, central-eastern Africa, continental southeastern Asia) that the SCM fails to capture. As a  
380 result, it overestimates the average land rainfall increase (Fig. S9a).

381 In the case of the CO<sub>2</sub>-induced land warming, the SCM overestimates the land rainfall increase  
382 on average (Fig. S9b). Both  $T_S$  and  $RH_S$  changes are of weak magnitudes, making it difficult to  
383 evaluate the sensitivity of the SCM to these changes. The resulting correlation coefficient between  
384 the patterns of Fig. 6c and 6d is very weak. Note that the strong rainfall increase over the Sahara

385 is not significant, because there are less than 6 months of the climatological year for which SCM  
386 runs correspond to this region and can be projected on it (not shown).

387 As mentioned above, the vegetation response to increased CO<sub>2</sub> reduces evapotranspiration and  
388 subsequently warms the surface over land. The effect of land-surface warming, detailed above,  
389 can now be switched off by fixing the land surface temperature. This allows us to isolate the  
390 effect of reduced evapotranspiration, which is to generally reduce rainfall over land (Fig. 6e).  
391 Both the pattern and magnitudes of land rainfall decreases are well captured by the SCM (Fig. 6f,  
392 Fig. S9c). This shows that the sensitivity of the SCM precipitation to  $RH_S$  is sensible. Note  
393 that for this particular projection, we only use variations in evaporation (using  $\beta$ ) to reconstruct  
394 the  $RH_S$  pattern (i.e. we fixed horizontal advection of moisture), simply for more relevance and  
395 consistency with the GCM forcing. However, here again the SCM fails to capture a few spots of  
396 land rainfall increases (the same as in the land-warming case: northeastern Brasil, central-eastern  
397 Africa, continental southeastern Asia). As a result, the average land rainfall decrease is slightly  
398 overestimated by the SCM over tropical America and more strongly over Asia and Oceania.

399 Overall, when forcing is applied over land as it is the case here, the SCM does not capture rainfall  
400 changes over the ocean, or over some land regions like northeastern Brazil, central-eastern Africa  
401 and continental southeastern Asia. This highlights the role of large-scale circulation changes that  
402 are independent from local surface changes and cannot be represented by the SCM. Over the  
403 eastern Amazon in particular, the crucial role of remotely-driven changes in low-level wind con-  
404 vergence, independent from local surface changes, has been shown by Saint-Lu et al. (2019). The  
405 SCM results are consistent with this idea that changes in the local surface temperature and evapo-  
406 ration do not dominate regional rainfall changes over land everywhere.

407 *b. Perturbed Sea Surface Temperature pattern*

408 Several studies have shown that changes in SST patterns drive most of the changes in rainfall  
409 patterns over the tropical oceans (Xie et al. 2010; Ma and Xie 2013; Chadwick et al. 2014; Kent  
410 et al. 2015). The pattern of the rainfall response to changes in the SST pattern is well captured by  
411 the SCM (correlation: 0.72), especially over the ocean (correlation: 0.77), as shown by Fig. 6g,h.  
412 Despite the strong sensitivity of the SCM precipitation to the SST, the magnitude of the rainfall  
413 response is also well captured, thanks to the reconstruction of the  $RH_5$  pattern via variations of  
414 moisture (not shown). When regressing linearly the SCM precipitation change on the GCM pre-  
415 cipitation change over the ocean (Fig. S10), the slope is very close to 1 with an origin very close  
416 to 0, confirming the good correspondence in the magnitudes of rainfall changes between the SCM  
417 and the GCM.

418 Overall, this result confirms the dominance of the warmer-get-wetter mechanism in the rainfall  
419 response to SST pattern changes over the tropical ocean in GCMs. In particular, the local effect  
420 of SST pattern change on convective instability appears to dominate over the influence of SST  
421 gradients on boundary layer pressure gradients [Lindzen and Nigam (1987) model], as this second  
422 effect is not well represented by the SCM.

423 Over land, the rainfall response to SST pattern changes is not well captured by the SCM. This  
424 is not surprising, since the GCM land rainfall responds to the change in the SST pattern via the  
425 atmosphere, with a top-down forcing—that we attempt to capture in the SCM with a bottom-up  
426 forcing (using the surface temperature and relative humidity). Recall that here, unlike for land-  
427 surface perturbations, only the ocean surface is prescribed in the GCM. Changes in the SST pattern  
428 directly drive circulation changes over land, which are thus not driven by the land surface. In this  
429 case, the only way the SCM can capture the GCM land rainfall changes is via their signatures on

430 the land surface; for example some drying over the Amazon is captured, probably because of the  
431 subsequent  $RH_S$  reduction.

### 432 *c. Perturbed atmospheric CO<sub>2</sub>*

#### 433 1) CIRCULATION WEAKENING

434 As shown in previous studies, the atmospheric overturning circulation weakens as a direct re-  
435 sponse to increased atmospheric CO<sub>2</sub> (Bony et al. 2013; He and Soden 2015; Chadwick et al.  
436 2014). Additional evidence for this is provided by the reduction of the vertically-integrated con-  
437 vective mass flux (positive upward,  $M_{INT}$ ) simulated by the GCM in response to the  $4\times\text{CO}_2$   
438 radiative-only forcing, especially over the ocean (Fig. 7a). Two important hypotheses to explain  
439 the CO<sub>2</sub>-induced circulation weakening are: (1) reduced radiative cooling, directly due to in-  
440 creased atmospheric CO<sub>2</sub>, heats the atmosphere and suppresses convection, reducing the convec-  
441 tive mass flux (i.e reduced radiative cooling has to be balanced by reduced convective heating)  
442 (Bony et al. 2013), (2) increasing CO<sub>2</sub> warms dry regions (especially the subtropics) more than  
443 convective regions, reducing energy transports between ascent and descent regions and slowing  
444 down the associated circulation. Merlis (2015) suggested that the troposphere warms more in dry  
445 regions than in wet regions because increasing CO<sub>2</sub> reduces radiative cooling more efficiently as  
446 there is less absorption overlap with water vapour and clouds. Both hypotheses could be captured  
447 by the SCM, as they involve local changes in radiative cooling.

448 Figure 7a shows the  $M_{INT}$  response to the  $4\times\text{CO}_2$  radiative-only direct effect, as simulated by  
449 the GCM and projected by the SCM, tropically averaged over ocean and over land. Here, we  
450 use the set of SCM experiments perturbed with increased atmospheric CO<sub>2</sub> (SCM\_4xCO2; see  
451 section 2.c), based on a  $4x\text{CO}_2$ -perturbed environment. In order to investigate the direct response  
452 of the SCM vertical convective mass flux to the  $4\times\text{CO}_2$  forcing,  $RH_S$  is left free to respond instead

453 of being prescribed from the GCM (this is done by keeping the same scaling coefficients for  
454 evaporation and moisture as in the reference experiment, see Methods; corresponding maps are  
455 given in Fig. S11a,b). Note that there are no  $T_S$  changes anyway since the surface is prescribed  
456 over land and ocean. When increasing  $\text{CO}_2$ , the SCM captures most of the convective mass flux  
457 weakening, as expected (Fig. 7a).

458 On average over land, the circulation weakening is a lot less pronounced than over the ocean  
459 in the GCM (Fig 7a). This is because over most land regions except South America, circulation  
460 actually strengthens in response to the  $4\times\text{CO}_2$  radiative-only forcing in the GCM (Fig. S11a). One  
461 possible explanation is that enhanced warming of the atmospheric column over desert regions rein-  
462 forces monsoon circulations, by increasing land-ocean pressure gradients (Chadwick et al. 2019).  
463 This hypothesis is supported by the fact that the SCM does not capture any circulation strengthen-  
464 ing over land (Fig. S11b), since it cannot reproduce such a direct atmospheric teleconnection that  
465 is not driven by surface warming.

## 466 2) RAINFALL RESPONSE

467 The rainfall response to the  $4\times\text{CO}_2$  radiative-only forcing (Fig. 6i) is strongly consistent with  
468 the convective mass flux response mentioned above: rainfall decreases over the ocean following  
469 the tropical circulation weakening and increases over land, presumably because of enhanced mon-  
470 soon systems associated with enhanced subtropical tropospheric warming. Over the ocean, the  
471 SCM only produces a very weak rainfall decrease over the southern Indian ocean, the western  
472 Atlantic and western Pacific and no clear noticeable change over the central-eastern Pacific. This  
473 is consistent with the SCM not fully capturing the circulation weakening, as mentioned above. It  
474 is also due to  $RH_S$  changes over the ocean: in the GCM,  $RH_S$  is increased over the ocean by the  
475 weakened circulation (Fig. S8a), probably because of moisture building up near the surface; but

476 in the SCM, increased  $RH_S$  tends to increase rainfall and counteract the rainfall reduction induced  
477 by the circulation weakening. Over land, the rainfall increase is captured by the SCM, thanks to  
478 the associated  $RH_S$  increase (Fig. S8a).

#### 479 *d. Uniform ocean warming*

##### 480 1) CIRCULATION WEAKENING

481 Previous studies have shown that the overturning circulation is also weakened by global surface  
482 warming (Knutson and Manabe 1995; Ma et al. 2012; He et al. 2014; He and Soden 2015). This  
483 is consistent with reduced  $M_{INT}$  across the whole tropics when a uniform +4 K ocean warming  
484 is applied in the GCM (Fig. 7b). This ocean warming-induced circulation weakening is thought  
485 to originate from increasing dry static stability ( $\partial\theta/\partial z$ ) in descent regions (Knutson and Manabe  
486 1995). When the surface warms by about 4 K, the troposphere warms even more, as dictated  
487 by the shape of moist adiabat which is maintained by convection in the tropics. This vertically  
488 non-uniform warming increases the dry static stability, which tends to increase dynamical heating  
489 ( $w\partial\theta/\partial z$ ). As dynamical heating and radiative cooling balance each other in descent regions, the  
490 limited increase in radiative cooling in descent regions limits the increase in dynamical heating  
491 and requires a reduction in the vertical motion  $w$ . By mass conservation, this weakens the whole  
492 overturning circulation. This process does not only involve the direct local response to increased  
493 dry static stability, but it also involves changes in mass transport that are not induced by local  
494 surface temperature, and are not captured by the WTG/DGW framework. Therefore, the SCM is  
495 not able to fully capture it.

496 Figure 7b shows the  $M_{INT}$  response to the uniform ocean +4 K warming, as simulated by the  
497 GCM and projected by the SCM tropically averaged over ocean and over land. Here, we use the  
498 set of SCM experiments perturbed with surface warming (SCM.4K; see section 2.c), based on

499 a +4K-perturbed environment (warmer and moister). In order to investigate the direct response  
500 of the SCM vertical circulation to the uniform ocean + 4 K warming,  $RH_S$  is left free to respond  
501 instead of being prescribed from the GCM (this is done by keeping the same scaling coefficients  
502 for evaporation and moisture as in the reference experiment, see Methods; corresponding maps  
503 are given in Supplementary Figure S11). When warming the surface (SCM\_4K) as in p4KSST, the  
504 SCM does not produce any circulation weakening (Fig. 7b), even over the ocean. As mentioned  
505 above, explicit connections between ascent and descent regions are missing in the SCM, making it  
506 unable to fully capture the circulation weakening. The SCM only locally captures the weakening  
507 of subsidence in descent regions, as required by the local balance between dynamical heating and  
508 radiative cooling with increased dry static stability (Supp. Fig. S12). Therefore, our results support  
509 the above mechanism to explain the ocean warming-induced circulation weakening; that is the idea  
510 that it is not a direct local response to increased stability, but to changes in mass transport between  
511 ascent and descent regions that are independent from local surface changes.

512 Over land, the SCM predicts a strong increase in circulation instead of the strong decrease sim-  
513 ulated by the GCM (Fig. 7b). A simple view to explain this result is that it follows enhanced land  
514 warming: with fixed moisture coefficients, the SCM DGW parametrization predicts that rainfall  
515 increases over land since land warms more than the ocean.

## 516 2) RAINFALL RESPONSE

517 In response to uniform ocean + 4 K warming, precipitation generally increases over the ocean  
518 following the wet-get-wetter mechanism (Chou et al. 2009) as shown in Fig. 6k. The SCM pro-  
519 duces a general rainfall increase over the ocean but strongly overestimates the magnitude (Fig. 6l).  
520 This is consistent with the SCM not capturing the ocean warming-induced circulation weakening,  
521 as mentioned above, that damps the wet-get-wetter response. Besides, our SCM set-up is not able

522 to represent the fact that as precipitation intensifies, it can decrease on its margins due to enhanced  
523 advective drying (Chou et al. 2009).

524 As when perturbing SST patterns, ocean warming directly drives circulation changes over land  
525 (top-down forcing), which are thus not driven by the land surface (bottom-up forcing) and are not  
526 expected to be captured by the SCM. However, ocean warming also indirectly drives land surface  
527 warming, with land warming more than the ocean, associated with reduced  $RH_S$  (Sutton et al.  
528 2007; Joshi et al. 2008; Dong et al. 2009; Lambert et al. 2011), as confirmed by Fig. S8d. Both en-  
529 hanced land-surface warming and reduced  $RH_S$  constitute a bottom-up forcing on the atmospheric  
530 column, which the SCM can capture. In the GCM, rainfall decreases over almost all tropical land  
531 in response to uniform ocean warming (Fig. 6k). Some studies suggest that this is caused by the  
532 decline of land  $RH_S$  (Fasullo 2012; Chadwick 2016; Lambert et al. 2017), in which case the land  
533 rainfall decrease would be a response to a bottom-up forcing, reproducible in the SCM.

534 Other studies emphasize the role of remote tropospheric forcing on local rainfall and surface  
535 temperature changes (Chiang and Sobel 2002; Joshi et al. 2008; Giannini 2010). Following these  
536 ideas, the land rainfall decrease could be driven by a top-down forcing. For example, tropospheric  
537 warming over land (transmitted from the ocean by atmospheric waves, consistent with the WTG  
538 approximation) could directly suppress convection by stabilizing the column. Atmospheric sta-  
539 bility over land cannot be fully diagnosed from the enhanced land warming, because of potential  
540 effects of both reduced  $RH_S$  and top-down atmospheric connections. Convection is already in-  
541 creased over the ocean, as a direct response to ocean warming; so it cannot be increased over land  
542 too, owing to mass and energy conservation. It can be viewed as the atmosphere over land being  
543 forced to import increased energy from the atmosphere over the ocean, as suggested by Lambert  
544 et al. (2011). Since radiative cooling over land can only increase by a limited amount, convection

545 over land ultimately decreases to reduce latent heating and conserve energy. The SCM would not  
546 capture such a top-down atmospheric connection.

547 The SCM fails to capture the land rainfall decrease in response to uniform ocean warming  
548 (Fig. 6l). Despite reduced land  $RH_S$ , the SCM produces the opposite response, with a strong  
549 intensification of rainfall over land. This could indicate that the land rainfall decrease is not a  
550 response to the bottom-up forcing associated with reduced  $RH_S$ ; but to a top-down forcing, as  
551 proposed above. However, it could also simply be a result of the SCM precipitation being overly  
552 sensitive to surface temperatures, especially given the strong magnitude of the enhanced land-  
553 surface warming in this case (not shown). As a result, it is possible that the effect of land-surface  
554 warming dominates over the effect of reduced  $RH_S$  in the SCM, even if the opposite happens in  
555 the GCM. This means that it is possible that the SCM fails to capture a bottom-up forcing, which  
556 it is theoretically able to capture, because of its too-strong sensitivity to the surface temperature.

557 We cannot firmly determine the reasons for the SCM failure to reproduce the land rainfall de-  
558 crease, but results are very consistent with Chadwick et al. (2019), who used two experiments  
559 isolating land-warming only from ocean-warming only. They showed that they did not add up  
560 linearly to the full ocean warming experiment, suggesting that forcing the atmosphere with land  
561 warming cannot capture the response of land rainfall to ocean warming.

## 562 **6. Conclusions**

563 This study uses a Single Column model (SCM) representing the Weak Temperature Gradient  
564 (WTG) approximation with the Damped Gravity Wave (DGW) parametrization and implemented  
565 with moisture variations, in order to investigate: 1) how much of the present-day mean tropical  
566 rainfall and circulation pattern is associated with  $T_S$  and  $RH_S$  patterns, 2) how much of the change

567 in the mean tropical rainfall pattern is associated with the change in the tropical mean-state envi-  
568 ronment and in the  $T_S$  and  $RH_S$  patterns.

569 Our first result is that most of the present-day mean tropical rainfall and circulation pattern  
570 is associated with  $T_S$  and  $RH_S$  patterns, confirming the relevance of the WTG approximation.  
571 We use the SCM to produce a rainfall pattern that is associated with  $T_S$  and  $RH_S$  patterns. We  
572 show that it captures much of the General Circulation Model (GCM) tropical mean rainfall pattern  
573 (correlation with HG3-AMIP of 0.71 over the whole tropics and 0.8 when considering only the  
574 ocean), although rainfall tends to extend too much spatially over the ocean. Previous studies have  
575 also found good correspondences between SCM and GCM rainfall (Sobel and Bretherton 2000;  
576 Zhu and Sobel 2012) but here we implement variations of moisture which considerably improve  
577 the rainfall representation, especially over land. Despite the overall good correspondence, the  
578 SCM precipitation is too sensitive to the surface temperature compared with the GCM. This is  
579 probably associated with the lack of variability and transients in the simulated single column,  
580 which is specific to SCMs under the WTG approximation. As a result, the SCM overestimates  
581 rainfall on average. Rainfall over the ocean is too spatially extended and generally too strong,  
582 while regions with low rain rates are too dry. Land regions are too dry, except for some rainforests.

583 Our second result is that the change in the mean tropical rainfall pattern cannot be fully associ-  
584 ated with the change in the tropical mean-state environment and in the  $T_S$  and  $RH_S$  patterns. The  
585 SCM does not successfully reproduce the rainfall response to the full  $\text{CO}_2$  forcing. In particular,  
586 it fails to limit the increase in rainfall over the ocean and to reproduce the rainfall decrease over  
587 land that occur when uniformly warming the ocean. This is, at least partly, because of the crucial  
588 role of circulation changes that are driven by remote surface changes through atmospheric tele-  
589 connections, highlighting the importance of top-down forcing (as opposed to bottom-up forcing).

590 However, the too-strong sensitivity of the SCM precipitation to the surface temperature could also  
591 play a role in these misrepresentations.

592 By analysing the differences between the SCM and the GCM, we were able to show that the  
593 weakening of the tropical atmospheric overturning circulation, which constrains rainfall changes,  
594 is only partly a direct local response to increasing  $CO_2$ : atmospheric teleconnections between as-  
595 cent and descent regions, that are independent from local surface changes, play a crucial role. The  
596 tropical atmospheric overturning circulation weakens partly as a direct response to the increased  
597 atmospheric  $CO_2$  and partly in response to the subsequent tropics-wide surface warming. These  
598 two cases (the direct radiative-only effect of  $4\times CO_2$  and the uniform ocean warming) are repro-  
599 duced in the SCM using two different sets of perturbed SCM runs, based on a perturbed RCE  
600 environment (either with increased  $CO_2$  or with +4 K surface warming). The SCM captures most  
601 of the circulation weakening that is due to the direct radiative effect of increased  $CO_2$ . However,  
602 it does not capture the circulation weakening that is due to the uniform surface warming. This  
603 suggests that it originates from static stability changes in descent regions, and also relies on at-  
604 mospheric teleconnections between descent and ascent regions, that are independent from local  
605 surface changes (and not fully captured by the SCM). The fact that the SCM does not represent  
606 top-down atmospheric teleconnections, which seem to play a key role in weakening the overturn-  
607 ing circulation, explains at least part of the misrepresentation of rainfall changes over the ocean  
608 (too much rainfall increase in response to ocean warming).

609 Even though the SCM does not successfully reproduce the full rainfall response to the  $CO_2$   
610 forcing, it does successfully reproduce the rainfall response to changes in the SST pattern only.  
611 We show that the rainfall response to changes in the SST pattern, which is the dominant part of the  
612 full rainfall change over the ocean, can be mostly associated with large-scale circulation changes  
613 driven by  $T_S$  and  $RH_S$  patterns, suggesting a dominant role for the local effect of SST pattern

614 change on convective instability (rather than the influence of SST gradients on boundary-layer  
615 pressure gradients).

616 The rainfall response to vegetation changes caused by the CO<sub>2</sub> increase, which are a dominant  
617 component of rainfall changes over tropical forest regions (Betts et al. 2004; Cao et al. 2012;  
618 Chadwick et al. 2017) can also be mostly associated with  $T_S$  and  $RH_S$  pattern changes. The SCM  
619 successfully reproduces the rainfall response to vegetation changes caused by the CO<sub>2</sub> increase.  
620 It reproduces rainfall increases over land when forced by land warming, rainfall decreases when  
621 forced by evaporation weakening, and even some of the Amazon drying that appears in response  
622 to land warming induced by vegetation changes. These results are reassuring, as they suggest  
623 that rainfall changes can be well diagnosed from changes in  $T_S$  and  $RH_S$ , when they are forced  
624 by perturbations in surface temperature and evaporation patterns. However, when the forcing  
625 is applied over land, the SCM does not capture rainfall changes over the ocean or over some  
626 land regions. This suggests that changes in the local surface temperature and evaporation do not  
627 dominate regional rainfall changes over land everywhere. Remotely-driven changes in low-level  
628 wind convergence, independent from local surface changes, can play a crucial role in some tropical  
629 land regions.

630 We cannot exclude the possibility that our SCM set-up, as a simplified representation of the  
631 WTG approximation, using an idealized parametrization in a one-dimensional model, biases our  
632 results, due to misrepresenting the sensitivity of rainfall to temperature and humidity. The goal  
633 of this study was not to perfectly reproduce the mean tropical rainfall pattern and its response to  
634 climate change, but to diagnose its drivers and better understand it. Further work is needed to  
635 confirm or disprove our hypotheses. To better represent land regions, the SCM could be coupled  
636 to a land-surface model. To test our hypothesis on land precipitation decreases, another set-up  
637 could be used by connecting a second column to the existing one, which would not be forced at

638 the surface but coupled to a land-surface model. Finally, our analyses could be replicated using  
639 GCM experiments performed with HadGEM3, the SCM's parent GCM, once they are available.  
640 Even though circulation weakening, for example, is a quite robust climate change response across  
641 models, this would give more confidence on the attribution of the differences between the SCM  
642 and the GCM results for climate change.

643 *Acknowledgments.* The authors would like to thank Adam Sobel and the two other anonymous  
644 reviewers for their comments and suggestions, that helped to substantially improve the quality of  
645 the manuscript. The authors thank Duncan Ackerley for producing of the prescribed-land AC-  
646 CESS simulations, and Peter Good, Hongyan Zhu, Christopher Holloway and Adam Sobel again  
647 for helpful advice and discussions. The ACCESS simulations were undertaken with the assistance  
648 of the resources from the National Computational Infrastructure (NCI), which is supported by the  
649 Australian Government. Data are publicly available from the NCI. Input surface temperature, soil  
650 moisture, and deep soil temperatures are also available from the NCI upon request. The relevant  
651 doi (and other metadata) for each of the individual experiments can be found in the supporting  
652 information attached to Ackerley et al. (2018). The authors thank the JASMIN and CEDA team  
653 for making available the JASMIN computing resource Lawrence et al. (2013). This work was  
654 supported by the UK Natural Environment Research Council, grant NE/N018486/1. Rob Chad-  
655 wick was supported by the Newton Fund through the Met Office Climate Science for Service  
656 Partnership Brazil (CSSP Brazil).

## 657 APPENDIX A

### 658 **Mathematical formulation of the Damped Gravity Wave parametrization and horizontal** 659 **advection schemes in the SCM**

660 *a. Damped Gravity Wave parametrization*

661 The DGW parametrization consists in providing a solution to the system of momentum, conti-  
 662 nuity and hydrostatic equations, that maintains weak free-tropospheric temperature gradients.

663 Our formulation of the DGW parametrization follows Kuang (2008), is described in Daleu et al.  
 664 (2015) and summarized in this section.

665 Considering the decomposition of a variable  $X$  into a mean-equilibrated value  $\bar{X}$  and a perturba-  
 666 tion  $X'$ , the 2D linearized perturbed equations of momentum, continuity and hydrostatic balance  
 667 can be written as:

$$\bar{\rho} \partial_t u' = -\partial_x p' - \varepsilon \bar{\rho} u' \quad (\text{A1})$$

$$\partial_x(\bar{\rho} u') + \partial_z(\bar{\rho} w') = 0 \quad (\text{A2})$$

$$\partial_z p' = \bar{\rho} g \frac{T'_v}{T_v} \quad (\text{A3})$$

668 Where  $\varepsilon$  is the mechanical damping of  $1 \text{ day}^{-1}$ .

669 This system is solved by assuming a solution in the form  $T' = \text{Re}(\hat{T} e^{-ikx})$ , describing the temper-  
 670 ature perturbation  $T'$  as vanishing with horizontal distance. This solution represents the horizontal  
 671 propagation of a gravity wave of a single wave number  $k=10^{-6} \text{ m}^{-1}$ , that maintains horizontal uni-  
 672 formity. We performed a few SCM runs using  $k=2 \cdot 10^{-6} \text{ m}^{-1}$  (another value used in the literature):  
 673 it does not make any noticeable difference (not shown).

674 In steady state, injecting this solution in the system yields:

$$\rho^{ref} w' = \int_z \int_z -\frac{k^2 \rho^{ref} g}{\varepsilon T_v^{ref}} T'_v dz^2 \quad (\text{A4})$$

675 In this framework, the vertical motion  $w'$  responds to temperature perturbations which horizon-  
676 tally vanish with respects to the WTG approximation by keeping hydrostatic equilibrium, conti-  
677 nuity and momentum conservation.

### 678 *b. Moisture advection*

679 We parametrize the horizontal advection of moisture from the environment into the simulated  
680 column. We define two terms of advection. The first one is the lateral drawing, describing the  
681 horizontal advection of moisture by the locally parametrized circulation. The second one is the  
682 moisture relaxation, representing the horizontal mixing of moisture through the mean rotational  
683 flow and transient eddies, unrelated to the circulation parametrized in the column. We argue they  
684 represent different processes and can be used together.

#### 685 1) LATERAL DRAWING

686 Following Daleu et al. (2015), horizontal advection of moisture induced by the vertical motion  
687 is defined as the drawing of the reference air into the simulated domain, at each vertical level:

$$\left(\frac{\partial q}{\partial t}\right)_{drawing} = \max\left(\frac{\partial \omega}{\partial p}, 0\right) (q^{ref} - q) \quad (A5)$$

688  
689 where  $\max(\partial_p \omega, 0)$  is non zero only if there is convergence into the simulated column.

#### 690 2) HORIZONTAL MIXING

691 Zhu and Sobel (2012) showed that the sensitivity of rainfall to surface temperature was better  
692 represented by relaxing the moisture profile towards the environment. By representing horizontal

693 mixing, this moisture relaxation scheme prevents the simulated domain from getting unrealistically  
694 different from its environment.

695 We implement the following moisture relaxation scheme in our SCM:

$$\left(\frac{\partial q}{\partial t}\right)_{mixing} = \frac{q_{ref} - q}{\tau_q} \quad (\text{A6})$$

696  
697 where  $\tau_q$  is the relaxation time-scale that we fix to 1 day. In annual mean, tropical surface  
698 waters can remain at approximately the same temperature (+/- 0.2 K) over a distance of the order  
699 of 500 km (not shown). In the SCM, surface winds are fixed at 5 m/s. It would take about 1.15 days  
700 for moisture to be transported by a mean flow of 5 m/s over 500 km. A time-scale of 1 day would  
701 then be typical of horizontal moisture mixing between the simulated domain and a surrounding  
702 environment, that is far enough to be independent of the former (i.e. not under the same regime).

## 703 APPENDIX B

### 704 **Methods for the projection of SCM results on a map**

705 To project a set of SCM runs (SCM\_CTRL, SCM\_4xCO2 or SCM\_4K) on the climatology of  
706 a GCM experiment, we consider the GCM surface temperatures ( $T_S$ ) anomalies to the tropical  
707 average SST (on 20N-20S), and the SCM  $T_S$  anomalies to  $T_S^{RCE}$ . In most cases, we will also  
708 consider GCM and SCM near-surface relative humidity values ( $RH_S$ ). SCM results,  $T_S$  and  $RH_S$   
709 are always time-means over the last 40 days of the run. Projections are all performed on every  
710 month of the mean annual cycle of the GCM climatology, and then averaged over the year to  
711 obtain the annual-mean projection.

- 712 • Projection using GCM  $T_S$  (Fig. 3b): on each grid-point, the SCM run that has the closest  $T_S$   
713 anomaly is projected.
- 714 • Projection using GCM  $T_S$  and  $RH_S$  (Fig. 3c, 6b,d,h,j,l): on each grid-point, the SCM run that  
715 has the closest  $T_S$  anomaly and  $RH_S$  is projected.
- 716 • Projection using GCM  $T_S$ , and using the same  $\beta$  and  $q$  profile scaling as for a reference  
717 projection, i.e. allowing no change in moisture coefficients (Fig. 7): on a reference projec-  
718 tion, of a given set of SCM runs (SCM\_REF) on  $T_S$  and  $RH_S$  from a given GCM experiment  
719 (GCM\_REF), one particular SCM run, that was performed using a unique combination of ( $T_S$ ,  
720  $\beta$ ,  $q$  profile scaling), is projected on one particular month and grid-point of GCM\_REF. Thus,  
721 each grid-point of each month is associated with one value of  $\beta$  ( $\beta_{ref}$ ) and one  $q$  profile scal-  
722 ing ( $q\_scaling_{ref}$ ), that can be stored. The new projection of a set of SCM runs (SCM\_PERT)  
723 on another GCM experiment (GCM\_PERT) is then performed doing the following: on each  
724 grid-point, the SCM\_PERT run that has the closest  $T_S$  anomaly and was performed using  $\beta_{ref}$   
725 and  $q\_scaling_{ref}$  is projected (i.e. the same  $\beta$  and  $q$  profile scaling as the SCM\_REF run  
726 projected on that same month and on that same grid-point of GCM\_REF).
- 727 • Projection using GCM  $T_S$  and  $RH_S$ , and using the same  $q$  profile scaling as for another pro-  
728 jection (Fig. 6f): the projection of a set of SCM runs (SCM\_PERT) on a GCM experiment  
729 (GCM\_PERT) is performed doing the following. On each grid-point, the SCM\_PERT run that  
730 has the closest  $T_S$  anomaly and  $RH_S$ , and that was performed using  $q\_scaling_{ref}$  is projected  
731 (i.e. the same  $q$  profile scaling as the SCM\_REF run projected on that same month and on  
732 that same grid-point of GCM\_REF). Only  $\beta$  is allowed to be different.

733 The conditions for projection on each grid-point, when applicable, are that the SCM and the  
734 grid-point  $T_S$  and  $RH_S$  are not different by more than the spatio-temporal standard-deviation of

735 the GCM  $T_S$  and  $RH_S$ , respectively (standard deviation of the flattened 12-months  $\times$  latitudes  $\times$   
736 longitudes array). As a result, it is possible that nothing projects on the grid-point.

TABLE 2. Definition of the different components of the  $4\times\text{CO}_2$  forcing from the experiments listed in Table 1.

Component	Definition
Uniform + 4 K ocean warming	p4KSST - piSST
SST pattern-only	a4SST - p4KSST
Land warming induced by $4\times\text{CO}_2$ radiative-only forcing	AMIP_PL_4xCO2rad - AMIP_PL
Vegetation-only forcing with prescribed land	AMIP_4xCO2tot_PL - AMIP_4xCO2rad_PL
Land warming induced by Vegetation-only forcing	AMIP_PL_4xCO2tot - AMIP_PL_4xCO2rad
$4\times\text{CO}_2$ radiative-only forcing with prescribed land	AMIP_4xCO2rad_PL - AMIP_PL

979 **LIST OF FIGURES**

- 980 **Fig. 1.** Schematic of the SCM with the DGW parametrization.  $\theta_{ref}$  and  $\theta$  are the reference and  
 981 simulated potential temperatures, respectively.  $q_{ref}$  is the reference specific humidity and  
 982  $w'$  is the parametrized vertical velocity. The dashed red line represents the potential tem-  
 983 perature profile once it has been relaxed towards the reference profile, via vertical advection  
 984 (represented by the thin red arrows) by the parametrized vertical velocity. . . . . 51
- 985 **Fig. 2.** (Top) Relationship between precipitation and SST in the SCM\_CTRL\_ $T_S$ -only runs (black  
 986 line) and in the GCM HG3-AMIP (boxes encompass 50% of the values between the 25<sup>th</sup>  
 987 and the 75<sup>th</sup> percentiles, median is plain bold, mean is dashed). Each SCM experiment  
 988 corresponds to one prescribed surface temperature value and one resulting equilibrated mean  
 989 precipitation (taken as the time-mean over the last 40 days of the 100 days-long run to keep  
 990 only the equilibrated period). Error bars are drawn between the 25<sup>th</sup> and the 75<sup>th</sup> percentiles  
 991 of the range of precipitation values occurring during the equilibrated period of the run. In  
 992 HG3-AMIP, boxes show the distribution of precipitation found for each SST bin, considering  
 993 all months and all oceanic grid-points of the tropics (20N-20S). Boxes are 0.5 K-wide and  
 994 correspond to the surface temperature values used in the SCM experiments. (Bottom) Same  
 995 but for the relationship between vertical velocity at 500 hPa and SST. . . . . 52
- 996 **Fig. 3.** Annual-mean precipitation in HG3-AMIP and from SCM runs. a) HG3-AMIP annual mean  
 997 precipitation. b) Projection of SCM\_CTRL\_ $T_S$ -only precipitation results on HG3-AMIP  $T_S$   
 998 (see Methods). c) Projection of SCM\_CTRL precipitation results on HG3-AMIP  $T_S$  and  
 999  $RH_S$  (see Methods). d) Difference between c) and a). Hatched regions are where there are  
 1000 less than 10 months of the climatological year for which SCM runs correspond to the region  
 1001 and can be projected on it. R on the bottom right is the Pearson pattern correlation with a);  
 1002 R(ocean) is computed over the ocean only. . . . . 53
- 1003 **Fig. 4.** SCM against GCM (HG3-AMIP) annual-mean precipitation. a) SCM\_CTRL\_ $T_S$ -only  
 1004 against HG3-AMIP (i.e. precipitation from Fig. 3b plotted against precipitation from Fig. 3a,  
 1005 taken over the whole tropics). b) SCM\_CTRL against HG3-AMIP (i.e. precipitation from  
 1006 Fig. 3c plotted against precipitation from Fig. 3a). Orange dots are land grid-points and blue  
 1007 dots are ocean grid-points. Corresponding linear regressions are shown for land (orange)  
 1008 and ocean (blue). The dashed black line shows the  $y=x$  one-to-one line. . . . . 54
- 1009 **Fig. 5.** Annual-mean precipitation responses to a combination of forcings in the GCM. a) Fully  
 1010 coupled response to increased atmospheric  $CO_2$ : abrupt4x $CO_2$  - piControl. b) Sum of the  
 1011 responses to six different components of the 4x $CO_2$  forcing, namely (1) the change in the  
 1012 SST pattern, (2) the land warming due to the 4x $CO_2$  radiative-only effect, (3) the effect of  
 1013 the plant physiological response to 4x $CO_2$  with prescribed  $T_S$  over land and ocean, (4) the  
 1014 land warming due to the plant physiological response to 4x $CO_2$ , (5) the 4x $CO_2$  radiative-  
 1015 only effect (no plant physiology) with prescribed  $T_S$  over land and ocean, and (6) the uni-  
 1016 form + 4 K ocean warming: a4SST - piSST + AMIP\_4xCO2tot\_PL + AMIP\_PL\_4xCO2tot -  
 1017 2\*AMIP\_PL. R is the Pearson pattern correlation between a) and b). . . . . 55
- 1018 **Fig. 6.** Annual-mean precipitation responses to different components of the 4x $CO_2$  forcing, in  
 1019 the GCM and from SCM runs. Each panel shows on the top the GCM rainfall re-  
 1020 sponse and on the bottom the corresponding SCM projection. When not specified  
 1021 otherwise, projections are done using  $T_S$  and  $RH_S$  (Methods). Hatched regions are  
 1022 where there are less than 10 months of the climatological year for which SCM runs  
 1023 correspond to the region and can be projected on it (for either one of the two pro-  
 1024 jections compared). R is the Pearson pattern correlation between the SCM projec-  
 1025 tion and the GCM; R(ocean) is when considering the ocean only; R(land) when con-

1026 sidering land only. a) AMIP\_PL\_4xCO2tot - AMIP\_PL\_4xCO2rad. b) [Projection of  
 1027 SCM\_CTRL on AMIP\_PL\_4xCO2tot] - [proj. of SCM\_CTRL on AMIP\_PL\_4xCO2rad].  
 1028 c) AMIP\_PL\_4xCO2rad - AMIP\_PL. d) [Proj. of SCM\_CTRL on AMIP\_PL\_4xCO2rad]  
 1029 - [proj. of SCM\_CTRL on AMIP\_PL]. e) AMIP\_4xCO2tot\_PL - AMIP\_4xCO2rad\_PL. f)  
 1030 [Proj. of SCM\_4xCO2 on AMIP\_4xCO2tot\_PL, done using  $T_S$  and  $RH_S$  and using the same  
 1031  $q$  profile scaling as for the proj. of SCM\_4xCO2 on AMIP\_4xCO2rad\_PL (so that only evap-  
 1032 oration is allowed to change; Methods)] - [proj. of SCM\_4xCO2 on AMIP\_4xCO2rad\_PL].  
 1033 g) a4SST - p4KSST. h) [Proj. of SCM\_4K on a4SST] - [proj. of SCM\_4K on p4KSST].  
 1034 i) AMIP\_4xCO2rad\_PL - AMIP\_PL. j) [Proj. of SCM\_4xCO2 on AMIP\_4xCO2rad\_PL] -  
 1035 [proj. of SCM\_CTRL on AMIP\_PL]. k) p4KSST - piSST. l) [Proj. of SCM\_4K on p4KSST]  
 1036 - [proj. of SCM\_CTRL on piSST]. . . . . 56

1037 **Fig. 7.** Annual-mean convective mass flux (positive upward,  $M_{INT}$ , left panel) and near-surface relative  
 1038 humidity ( $RH_S$ , right panel) responses to different components of the  $4 \times \text{CO}_2$  forcing,  
 1039 in the GCM and from SCM runs. The top and bottom panels correspond to two compo-  
 1040 nents of the forcing indicated in the panels titles. Each shows GCM responses (plain bars)  
 1041 and corresponding SCM projections (circled-patterned bars) with fixed moisture coefficients  
 1042 (details hereafter), averaged over tropical (20N-20S) ocean (blue bars) and land (orange  
 1043 bars). a) and c) GCM: AMIP\_4xCO2rad\_PL - AMIP\_PL; SCM: [Projection of SCM\_4xCO2  
 1044 on AMIP\_4xCO2rad\_PL, done using  $T_S$  only and using the same  $\beta$  and  $q$  profile scaling as  
 1045 for the projection of SCM\_CTRL on AMIP\_PL (Methods)] - [projection of SCM\_CTRL  
 1046 on AMIP\_PL (done using  $T_S$  and  $RH_S$ ; Methods)]. b) and d) GCM: p4KSST - piSST;  
 1047 SCM: [Projection of SCM\_4K on p4KSST, done using  $T_S$  only and using the same  $\beta$  and  
 1048  $q$  profile scaling as for the projection of SCM\_CTRL on piSST (Methods)] - projection of  
 1049 SCM\_CTRL on piSST (done using  $T_S$  and  $RH_S$ ; Methods). . . . . 57

1050 FIG. 1. Schematic of the SCM with the DGW parametrization.  $\theta_{ref}$  and  $\theta$  are the reference and simulated  
 1051 potential temperatures, respectively.  $q_{ref}$  is the reference specific humidity and  $w'$  is the parametrized vertical  
 1052 velocity. The dashed red line represents the potential temperature profile once it has been relaxed towards the  
 1053 reference profile, via vertical advection (represented by the thin red arrows) by the parametrized vertical velocity.

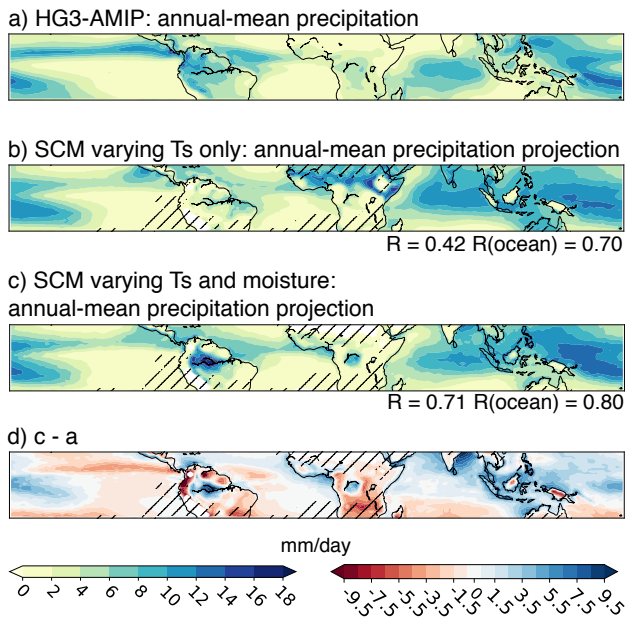

a) Precipitation against SST

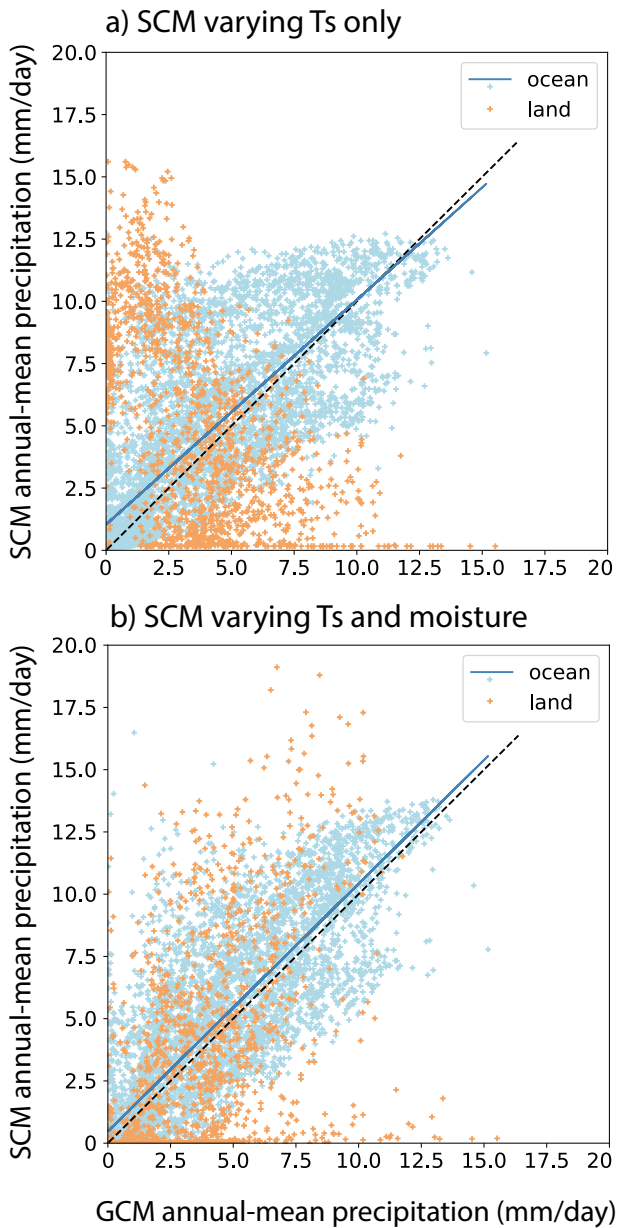

b) Vertical velocity at 500 hPa against SST

1054 FIG. 2. (Top) Relationship between precipitation and SST in the SCM\_CTRL\_ $T_S$ -only runs (black line) and in  
 1055 the GCM HG3-AMIP (boxes encompass 50% of the values between the 25<sup>th</sup> and the 75<sup>th</sup> percentiles, median is  
 1056 plain bold, mean is dashed). Each SCM experiment corresponds to one prescribed surface temperature value and  
 1057 one resulting equilibrated mean precipitation (taken as the time-mean over the last 40 days of the 100 days-long  
 1058 run to keep only the equilibrated period). Error bars are drawn between the 25<sup>th</sup> and the 75<sup>th</sup> percentiles of the  
 1059 range of precipitation values occurring during the equilibrated period of the run. In HG3-AMIP, boxes show  
 1060 the distribution of precipitation found for each SST bin, considering all months and all oceanic grid-points of  
 1061 the tropics (20N-20S). Boxes are 0.5 K-wide and correspond to the surface temperature values used in the SCM  
 1062 experiments. (Bottom) Same but for the relationship between vertical velocity at 500 hPa and SST.

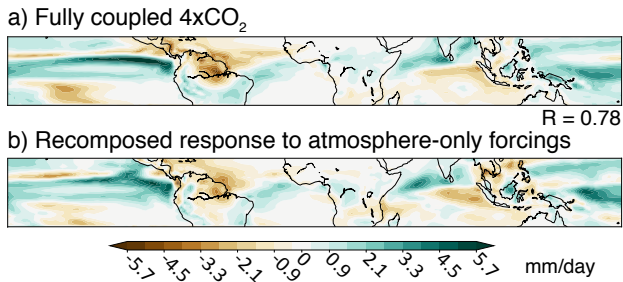

1063 FIG. 3. Annual-mean precipitation in HG3-AMIP and from SCM runs. a) HG3-AMIP annual mean precipita-  
 1064 tion. b) Projection of SCM\_CTRL\_ $T_S$ -only precipitation results on HG3-AMIP  $T_S$  (see Methods). c) Projection  
 1065 of SCM\_CTRL precipitation results on HG3-AMIP  $T_S$  and  $RH_S$  (see Methods). d) Difference between c) and  
 1066 a). Hatched regions are where there are less than 10 months of the climatological year for which SCM runs  
 1067 correspond to the region and can be projected on it. R on the bottom right is the Pearson pattern correlation with  
 1068 a); R(ocean) is computed over the ocean only.

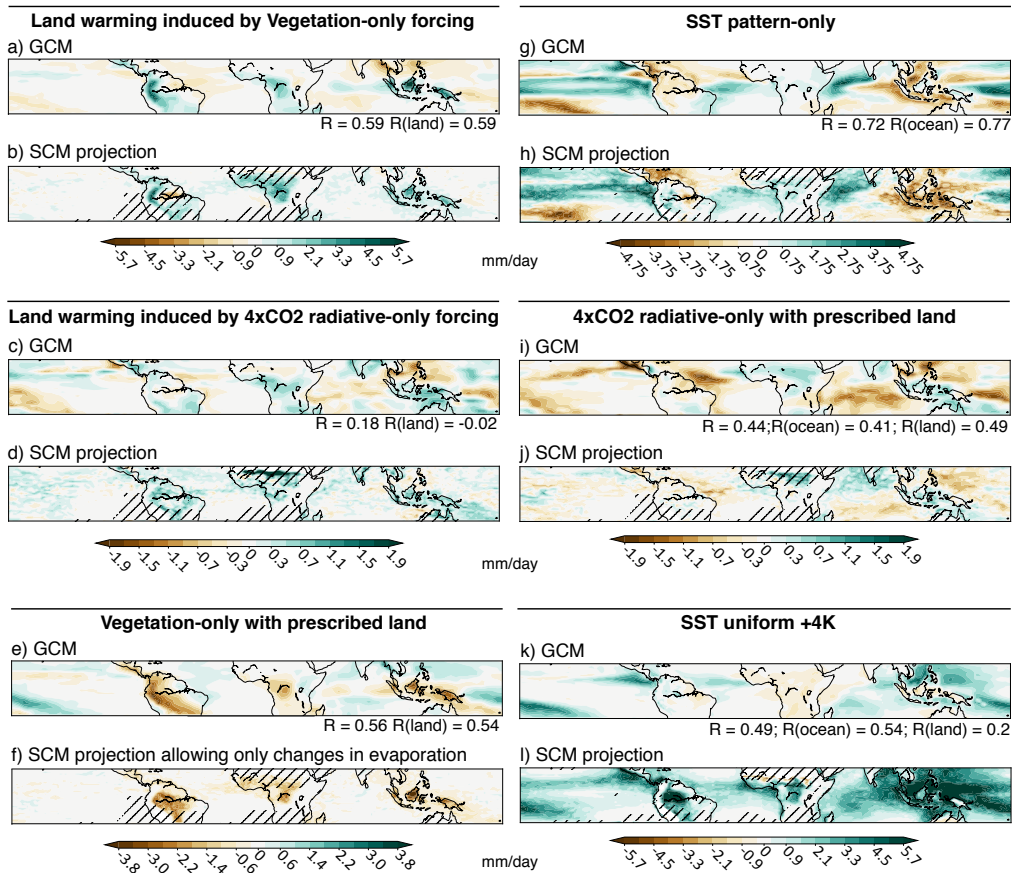

1069 FIG. 4. SCM against GCM (HG3-AMIP) annual-mean precipitation. a) SCM\_CTRL\_ $T_s$ -only against HG3-  
 1070 AMIP (i.e. precipitation from Fig. 3b plotted against precipitation from Fig. 3a, taken over the whole tropics).  
 1071 b) SCM\_CTRL against HG3-AMIP (i.e. precipitation from Fig. 3c plotted against precipitation from Fig. 3a).  
 1072 Orange dots are land grid-points and blue dots are ocean grid-points. Corresponding linear regressions are shown  
 1073 for land (orange) and ocean (blue). The dashed black line shows the  $y=x$  one-to-one line.

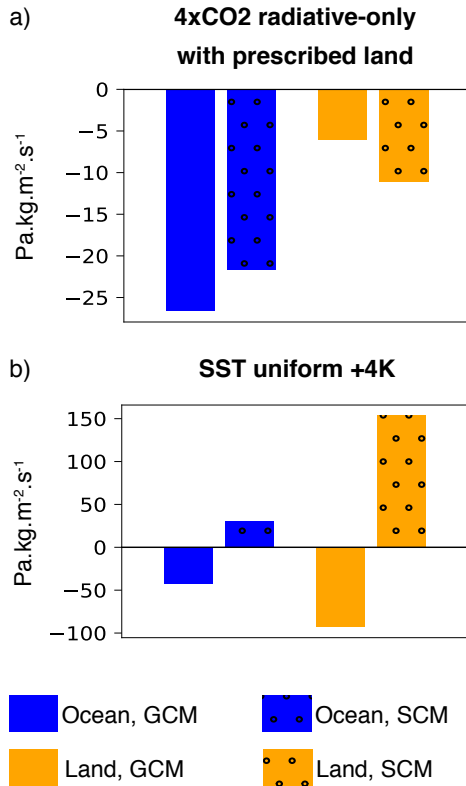

1074 FIG. 5. Annual-mean precipitation responses to a combination of forcings in the GCM. a) Fully coupled  
 1075 response to increased atmospheric  $\text{CO}_2$ : abrupt $4\times\text{CO}_2$  - piControl. b) Sum of the responses to six different  
 1076 components of the  $4\times\text{CO}_2$  forcing, namely (1) the change in the SST pattern, (2) the land warming due to the  
 1077  $4\times\text{CO}_2$  radiative-only effect, (3) the effect of the plant physiological response to  $4\times\text{CO}_2$  with prescribed  $T_S$   
 1078 over land and ocean, (4) the land warming due to the plant physiological response to  $4\times\text{CO}_2$ , (5) the  $4\times\text{CO}_2$   
 1079 radiative-only effect (no plant physiology) with prescribed  $T_S$  over land and ocean, and (6) the uniform +4 K  
 1080 ocean warming: a4SST - piSST + AMIP\_4xCO2tot.PL + AMIP.PL\_4xCO2tot - 2\*AMIP.PL. R is the Pearson  
 1081 pattern correlation between a) and b).

1082 FIG. 6. Annual-mean precipitation responses to different components of the  $4\times\text{CO}_2$  forcing, in the GCM and  
 1083 from SCM runs. Each panel shows on the top the GCM rainfall response and on the bottom the corresponding  
 1084 SCM projection. When not specified otherwise, projections are done using  $T_S$  and  $RH_S$  (Methods). Hatched  
 1085 regions are where there are less than 10 months of the climatological year for which SCM runs correspond to  
 1086 the region and can be projected on it (for either one of the two projections compared). R is the Pearson pattern  
 1087 correlation between the SCM projection and the GCM; R(ocean) is when considering the ocean only; R(land)  
 1088 when considering land only. a) AMIP\_PL\_4xCO2tot - AMIP\_PL\_4xCO2rad. b) [Proj. of SCM\_CTRL on  
 1089 AMIP\_PL\_4xCO2tot] - [proj. of SCM\_CTRL on AMIP\_PL\_4xCO2rad]. c) AMIP\_PL\_4xCO2rad - AMIP\_PL. d)  
 1090 [Proj. of SCM\_CTRL on AMIP\_PL\_4xCO2rad] - [proj. of SCM\_CTRL on AMIP\_PL]. e) AMIP\_4xCO2tot\_PL  
 1091 - AMIP\_4xCO2rad\_PL. f) [Proj. of SCM\_4xCO2 on AMIP\_4xCO2tot\_PL, done using  $T_S$  and  $RH_S$  and using  
 1092 the same  $q$  profile scaling as for the proj. of SCM\_4xCO2 on AMIP\_4xCO2rad\_PL (so that only evaporation  
 1093 is allowed to change; Methods)] - [proj. of SCM\_4xCO2 on AMIP\_4xCO2rad\_PL]. g) a4SST - p4KSST. h)  
 1094 [Proj. of SCM\_4K on a4SST] - [proj. of SCM\_4K on p4KSST]. i) AMIP\_4xCO2rad\_PL - AMIP\_PL. j) [Proj. of  
 1095 SCM\_4xCO2 on AMIP\_4xCO2rad\_PL] - [proj. of SCM\_CTRL on AMIP\_PL]. k) p4KSST - piSST. l) [Proj. of  
 1096 SCM\_4K on p4KSST] - [proj. of SCM\_CTRL on piSST].

1097 FIG. 7. Annual-mean convective mass flux (positive upward,  $M_{INT}$ , left panel) and near-surface relative  
 1098 humidity ( $RH_S$ , right panel) responses to different components of the  $4\times\text{CO}_2$  forcing, in the GCM and from  
 1099 SCM runs. The top and bottom panels correspond to two components of the forcing indicated in the panels  
 1100 titles. Each shows GCM responses (plain bars) and corresponding SCM projections (circled-patterned bars)  
 1101 with fixed moisture coefficients (details hereafter), averaged over tropical (20N-20S) ocean (blue bars) and  
 1102 land (orange bars). a) and c) GCM: AMIP\_4xCO<sub>2</sub>rad\_PL - AMIP\_PL; SCM: [Projection of SCM\_4xCO<sub>2</sub> on  
 1103 AMIP\_4xCO<sub>2</sub>rad\_PL, done using  $T_S$  only and using the same  $\beta$  and  $q$  profile scaling as for the projection  
 1104 of SCM\_CTRL on AMIP\_PL (Methods)] - [projection of SCM\_CTRL on AMIP\_PL (done using  $T_S$  and  $RH_S$ ;  
 1105 Methods)]. b) and d) GCM: p4KSST - piSST; SCM: [Projection of SCM\_4K on p4KSST, done using  $T_S$  only  
 1106 and using the same  $\beta$  and  $q$  profile scaling as for the projection of SCM\_CTRL on piSST (Methods)] - projection  
 1107 of SCM\_CTRL on piSST (done using  $T_S$  and  $RH_S$ ; Methods).
