## Abstract

Restrictions as a result of the COVID-19 pandemic have led to fewer vehicles on UK roads. Since fuel combustion is responsible for a large fraction of UK emissions it is expected that surface NO<sub>2</sub> concentrations would reduce as a result. However, over parts of the UK, surface NO<sub>2</sub> concentrations have increased following the implementation of travel restrictions. NO<sub>2</sub> measurements from 142 Automatic Urban and Rural Network sites are combined with meteorological data from the Met Office high-resolution weather prediction model to build site specific models. These models predict NO<sub>2</sub> concentrations given no change in emissions. It is found that both meteorological and emission changes contribute to the observed changes in NO<sub>2</sub> concentrations. Given no change in emissions, changes in meteorology between pre- and post-lockdown periods would have led to a mean increase in NO<sub>2</sub> concentrations of +6%. Conversely, changes in emissions would have led to a mean reduction in NO<sub>2</sub> concentrations of -18%, resulting in the observed total change in NO<sub>2</sub> concentrations of -12%. However at some sites the reduction in emissions is smaller than the increase in NO<sub>2</sub> concentrations due to meteorology. The largest increases associated with changes in the meteorology are seen at rural sites (+20%) where NO<sub>2</sub> measurements are representative of large areas and thus dominated by the regional advection of secondary NO<sub>2</sub> from Europe. Conversely, the largest decreases associated with reduced emissions are found at urban traffic and urban background sites (-27% and -14% respectively) where NO<sub>2</sub> concentrations are representative of local areas and thus dominated by local reduction in emissions from vehicles. As lockdown measures are relaxed, NO<sub>2</sub> concentrations are likely to return to pre-COVID levels, but these results demonstrate that changes in our behaviour can result in positive impacts on air quality and illustrate the effectiveness of travel-reducing strategies in urban areas.

## 1. Introduction

The coronavirus disease 2019 (COVID-19) outbreak began in late 2019 and by March 2020 the virus had been declared a global pandemic by the World Health Organization (WHO 2020). COVID-19 is a respiratory disease which may lead to pneumonia with symptoms such as fever, cough and shortness of breath. Countries all over the world have implemented lockdown restrictions to slow down its infection and mitigate its effects. These restrictions have caused an unprecedented reduction in global economic activity and travel (Nicola *et al* 2020).

One of the pollutants that is important for air quality is nitrogen dioxide (NO<sub>2</sub>) which is emitted by fuel combustion (Carslaw and Beevers 2005, Carslaw *et al* 2011). Exposure to high concentrations of NO<sub>2</sub> can aggravate respiratory diseases leading to increased hospital admissions (Mann *et al* 2002). In the UK, road transport is the largest source of NO<sub>2</sub> emissions. NO<sub>2</sub> is also formed in the atmosphere in a chemical reaction between nitric oxide (NO) and ozone (O<sub>3</sub>). Because this NO<sub>2</sub> is not released straight into the atmosphere, but is formed there by a chemical reaction, it is known as secondary NO<sub>2</sub>. Both primary emissions and secondary formation influence NO<sub>2</sub> concentrations. In addition, NO<sub>2</sub> can be

converted into nitric acid and nitrate aerosol, which are removed from the atmosphere by dry and wet deposition processes, or it can undergo photolysis leading to the destruction of  $\text{NO}_2$ . Meteorology can also have a significant influence on  $\text{NO}_2$  concentrations. Strong wind conditions lead to the dispersion of  $\text{NO}_2$  away from sources, while calm conditions lead to its accumulation. Meteorology also modifies atmospheric chemistry processes such as photolysis and wet deposition. The combination of these processes can make it difficult to identify the contribution from individual components on  $\text{NO}_2$  concentrations.

Analysis of satellite and ground-based measurement data has shown that  $\text{NO}_2$  concentrations in some countries has reduced by between 10 and 50% during the COVID-19 lockdown (Muhammad *et al* 2020, Berman and Ebisu 2020, Sharma *et al* 2020, Bauwens *et al* 2020). For example, Venter *et al* (2020) found declines in ground level  $\text{NO}_2$  in 27 countries of  $-29 \pm 15\%$ . Thus there is a large amount of spatial variability in the estimated  $\text{NO}_2$  concentration reductions. This variability is driven partly by the varying lockdown restrictions and partly because ground-level measurements of  $\text{NO}_2$  concentration are determined by a number of factors. These include (i) the magnitude and proximity of primary  $\text{NO}_2$  emissions to the measurement site, (ii) the chemistry leading to subsequent formation and destruction of  $\text{NO}_2$  and (iii) the dispersion and transport of  $\text{NO}_2$ . The aim of this study is to quantify the differences in  $\text{NO}_2$  concentrations that result from changes in emissions and changes in the meteorology.

The UK is positioned at the western edge of the European continent. The prevailing wind direction is westerly leading to the advection of relatively clean air over the UK from the North Atlantic. However, during high pressure conditions in western Europe, anti-cyclonic circulation can result in easterly advection of relatively polluted air from the European continent over the UK (Pope *et al* 2014). Under certain synoptic conditions, changes in meteorology can mask any changes in  $\text{NO}_2$  resulting from changes in emissions. This study investigates the spatial variability of  $\text{NO}_2$  concentration changes over the UK prior to and after the COVID-19 travel restriction were implemented on the 16 March 2020.

The total change in  $\text{NO}_2$  concentrations is partitioned into components associated with the varying meteorology and changing emissions. In order to investigate the spatial variability in surface  $\text{NO}_2$  concentrations it is necessary to build accurate site specific models using long timeseries of high spatial and temporal resolution meteorological and air quality information. This study uses over 5-years of air quality data from the Automatic Urban and Rural Network (AURN) in the UK (section 2). The air quality data is combined with over 5-years of high spatial resolution (1.5 km) meteorological data from the Met Office variable resolution model (UKV) (section 3).

**Figure 1.** Location of AURN sites measuring  $\text{NO}_2$ . The sites are classified as rural background (red), suburban background (green), urban background (yellow) and urban traffic (blue).

Site specific models are built to predict surface  $\text{NO}_2$  concentrations for 142 AURN stations (section 4). The impact of changing meteorology and emissions and the spatial variability in surface  $\text{NO}_2$  concentration changes described in section 5. Finally, the conclusions are found in section 6.

## 2. Data

### 2.1. Air quality data

The hourly air quality data used in this study comes from the Automatic Urban and Rural Network (AURN). The AURN includes automatic air quality monitoring stations measuring a range of atmospheric pollutants which undergo routine quality control. These sites provide hourly information which is communicated to the public via the Department for Environment, Food and Rural Affairs (DEFRA) website (DEFRA 2020). In this study we use hourly  $\text{NO}_2$  concentrations which are measured using chemiluminescence detectors. Currently there are 142 AURN sites measuring  $\text{NO}_2$  with the majority of sites classified as urban traffic (70), urban background (65) or rural background (21) (figure 1). Urban sites are located in built-up areas containing buildings with at least 2 floors. As a result, urban sites typically measure air quality which is representative of only a few  $\text{km}^2$ . Rural sites are located more than 5 km from built-up areas, industrial installations or major roads. The air sampled by rural sites is therefore representative of air quality in a surrounding area of 1000  $\text{km}^2$  (AURN 2020). The pollution levels measured at traffic sites are determined predominantly by the emissions from nearby traffic (Carslaw and Beevers 2004) whereas the pollution levels measured at background sites are not influenced significantly by any single source or street, but rather by the integrated contribution from all sources upwind of the station (Donnelly *et al* 2015).

## 2.2. Meteorological data

The hourly meteorological data used to build the statistical models in this study comes from the UK Met Office UKV model for the period 01/01/15 - 30/04/20. The UKV is a variable resolution UK model which has a high resolution inner domain (1.5 km grid boxes) over the area of forecast interest, separated from a coarser grid (4 km) near the boundaries by a variable resolution transition zone (Tang *et al* 2013). There are 70 vertical levels on a terrain-following hybrid-height vertical co-ordinate with Charney-Philips staggering. Sub-grid scale processes such as, boundary layer turbulence, radiation, cloud, microphysics and orographic drag are represented by parameterizations. The UKV has an advantage in that it contains a better representation of orography and other land surface parameters than coarser resolution models. Hourly 4D-Var assimilation allows the model to be initialised every hour to produce state-of-the-art weather forecasts for the UK (Ballard *et al* 2016). Meteorological data for the 5-year period (01/01/15 - 31/12/19) is extracted from the UKV and interpolated to the location of the AURN sites to build the statistical models described in section 4.

## 2.3. AQUM

The UK Met Office's Air Quality model (AQUM) is used in this study to simulate the regional transport of NO<sub>2</sub>. AQUM is the operational air quality forecast model for the UK (Savage *et al* 2013). The model has a 12 km horizontal grid spacing covering much of Western Europe. There are 70 vertical levels up to a model top height of 40 km. The model's meteorological fields are initialised with data from the Met Office global model. The chemistry fields are initialised with data based on the 24-hour forecast from the previous day (Davis *et al* 2014). Boundary conditions for meteorology and chemistry come from the Met Office global model forecast and Copernicus Atmosphere Monitoring Service global forecasts respectively (CAMS 2020). Emissions of NO<sub>2</sub> within the AQUM domain are generated by merging two data sets: the 2017 National Atmospheric Emissions Inventory (NAEI) (1 × 1 km) for the UK and 2017 European Monitoring and Evaluation Programme (EMEP) (0.1 × 0.1 degrees) for the rest of the model domain.

A quantitative evaluation of the ability of AQUM to capture the regional spatial distribution of NO<sub>2</sub> when sampled under the Lamb weather types, was performed by Pope *et al* (2015). Lamb weather types are an objective classification of midday UK circulation patterns (Lamb 1972). Pope *et al* (2015) found that AQUM could reproduce the large-scale accumulation of tropospheric column NO<sub>2</sub> over the UK under anticyclonic conditions and that transport is an important factor in governing the variability of UK air quality on synoptic timescales. AQUM is used in this study to qualitatively visualise the

regional transport of NO<sub>2</sub>, therefore emissions have not be altered to reflect post-lockdown emissions changes.

## 3. Synoptic overview of the pre- and post-lockdown periods

To gain an understanding of the meteorological situation this section provides a brief overview of the changes in the synoptic situation between the pre-lockdown period (01/02/20 - 16/03/20) and the post-lockdown period (17/03/20 - 30/04/20). Figure 2(a) shows the change in mean sea level pressure between the post- and pre-lockdown periods. The post-lockdown period was dominated by several persistent high pressure periods resulting in an increase in mean sea level pressure of 10-15 hPa over the whole of the UK. As a result of reduced horizontal pressure gradient the mean wind speed reduced by 1-2 ms<sup>-1</sup> during the post-lockdown period over the whole of the UK (figure 2(b)). Reduced wind speeds typically reduce dispersion which can cause NO<sub>2</sub> to accumulate close to its source (Bower *et al* 1994). During the pre-lockdown period the wind direction was dominated by south-westerlies and the advection of clean north Atlantic air over the UK (figure 2(c)). During the post-lockdown period there was an increase in the frequencies of easterlies (figure 2(d)), which typically results in the advection of polluted air from Europe over the UK containing high concentrations of secondary NO<sub>2</sub>.

## 4. Method

### 4.1. Multiple linear regression modelling

In order to predict hourly NO<sub>2</sub> concentrations during the ongoing COVID-19 travel restrictions multiple linear regression models are built using up to 5-years of AURN and UKV data (2015-2019) similar to the method of Shi and Harrison (1997). The models predict the hourly NO<sub>2</sub> concentrations we would expect, during the COVID-19 period, given no change in NO<sub>2</sub> emissions. Several meteorological and temporal explanatory variables are used to predict NO<sub>2</sub> concentrations at each AURN station.

The Akaike Information Criterion (AIC) is used to determine which explanatory variables to include in our model. The model with the lowest AIC score is expected to have the best balance between its ability to fit the data set and its ability to avoid over-fitting the data set. The explanatory variables used in this study are shown in table 1. Some explanatory variables are cyclic not linear, such as wind direction (i.e. 0 and 360 degrees have the same direction). To account for this, wind direction is partitioned into its northerly and easterly components. Similarly, several of the temporal variables are cyclic. For day of year, day of week and hour of day a cyclic relationship is assumed with

**Figure 2.** (a) Change in mean pressure between post- and pre-lockdown period. (b) Change in mean wind speed between post- and pre-lockdown period. (c) Mean wind speed and direction during pre-lockdown period. (d) Mean wind speed and direction during post-lockdown period.

**Table 1.** Summary of explanatory variables used to predict NO<sub>2</sub>. \* indicates cyclic variables.

Meteorological data	Temporal data
Temperature (K)	Date
Pressure (Pa)	Day of year*
Wind speed (ms <sup>-1</sup> )	Day of week*
Wind direction*	Hour of day*
Surface Heat Flux (Wm <sup>-2</sup> )	

fixed periods of 365 days, 7 days and 24 hours respectively.

#### 4.2. Partitioning of NO<sub>2</sub> concentration changes

Changes in NO<sub>2</sub> concentrations between the pre- and post-lockdown period may be due to changes in the primary emission of NO<sub>2</sub>, changes in the concentration of chemical precursors which can transform to produce secondary NO<sub>2</sub> (i.e. NO and O<sub>3</sub>), changes in the meteorology which affects the transport and mixing of NO<sub>2</sub> and its precursors, or a combination of all three. Differentiating changes in primary from secondary NO<sub>2</sub> is not possible using multiple linear regression modelling. Instead we focus on partitioning the differences attributed to changes in emissions

( $\Delta$  NO<sub>2</sub> Emissions) from changes in the meteorology ( $\Delta$  NO<sub>2</sub> Meteorology).

The statistical models described in section 4 are used to predict hourly NO<sub>2</sub> concentrations for the period 01/02/20–30/04/20. The model predictions assume no change in the emission of primary NO<sub>2</sub> or the emission of chemical precursors which transform to produce secondary NO<sub>2</sub>. We partition the contribution to change in NO<sub>2</sub> between the post- and pre-lockdown period as follows:

- (a)  $\Delta$  NO<sub>2</sub> Total: The difference between mean measured post-lockdown NO<sub>2</sub> concentrations (NO<sub>2</sub><sup>post</sup>) and mean measured pre-lockdown concentrations (NO<sub>2</sub><sup>pre</sup>) are compared to the 5-year averaged NO<sub>2</sub> concentrations for the period 1 February - 30 April ( $\overline{NO_2}$ ) at each AURN site.

$$\Delta NO_2 \text{ Total} = \frac{NO_2^{post} - NO_2^{pre}}{\overline{NO_2}} \quad (1)$$

- (b)  $\Delta$  NO<sub>2</sub> Meteorology: The difference between mean predicted post-lockdown NO<sub>2</sub> concentrations ( $\widehat{NO_2}^{post}$ ) and mean measured pre-lockdown concentrations are compared to

**Figure 3.** Data from 142 AURN measurement sites. (a) Mean NO<sub>2</sub> from 01/02/20 - 16/3/20 (pre-lockdown), (b) mean NO<sub>2</sub> from 17/03/20 - 30/04/20 (post-lockdown), (c) total percentage difference between post- and pre-lockdown periods.

5-year averaged NO<sub>2</sub> concentrations. The percentage change is attributed to changes in the meteorology.

$$\Delta \text{NO}_2 \text{ Meteorology} = \frac{\widehat{\text{NO}}_2^{\text{post}} - \widehat{\text{NO}}_2^{\text{pre}}}{\widehat{\text{NO}}_2} \quad (2)$$

- (c)  $\Delta \text{NO}_2$  Emissions: The difference between mean predicted post-lockdown NO<sub>2</sub> concentrations and mean measured post-lockdown NO<sub>2</sub> concentrations are compared to the 5-year averaged NO<sub>2</sub> concentrations. The percentage change is attributed to the changes in the emission of primary NO<sub>2</sub> or the emission of chemical precursors which transform to produce secondary NO<sub>2</sub>.

$$\Delta \text{NO}_2 \text{ Emissions} = \frac{\text{NO}_2^{\text{post}} - \widehat{\text{NO}}_2^{\text{post}}}{\widehat{\text{NO}}_2} \quad (3)$$

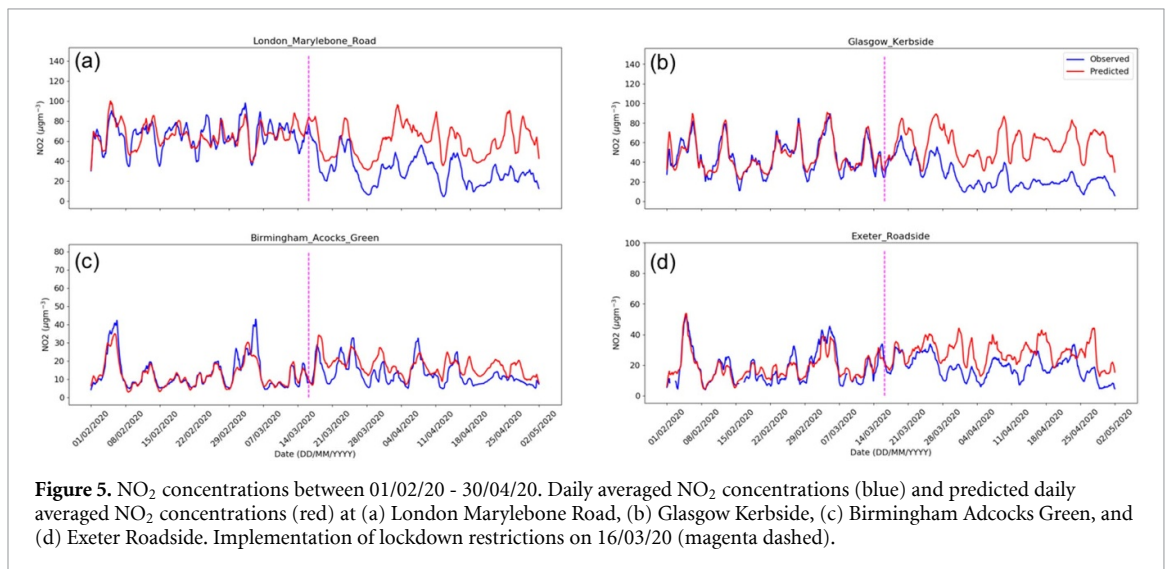

## 5. Results

### 5.1. Percentage change in total NO<sub>2</sub> concentrations ( $\Delta \text{NO}_2$ Total)

The mean NO<sub>2</sub> concentrations at 142 AURN sites are analysed for the pre-lockdown (01/02/20 - 16/03/20, figure 3(a)) and post-lockdown (17/03/20 - 30/04/20, figure 3(b)) periods. It is clear that since lockdown, NO<sub>2</sub> concentrations have reduced over much of the UK. Figure 3(c) shows the percentage change between the post- and pre-lockdown periods ( $\Delta \text{NO}_2$  Total). In the north of England NO<sub>2</sub> concentrations have reduced by an average of 20%, but in the south of England and parts of Wales, several AURN sites show an increase in NO<sub>2</sub> concentrations after lockdown of over 20%.

Figure 4 shows the time series of measured NO<sub>2</sub> concentrations at 6 sites in the UK. At all sites the NO<sub>2</sub> concentrations are below the 5-year average for much of the period studied. Figures 4(a) and (b) are

for the London Marylebone Road and Glasgow Kerbside urban traffic AURN sites respectively. At London Marylebone Road the change in NO<sub>2</sub> concentrations before and after lockdown was  $-36\mu\text{g}\text{m}^{-3}$  and at Glasgow Kerbside NO<sub>2</sub> concentrations changed by  $-20\mu\text{g}\text{m}^{-3}$ . This corresponds to a percentage change relative to the 5-year average of  $-42\%$  and  $-30\%$  respectively. Thus the anticipated decrease in NO<sub>2</sub> concentrations due to reduced emissions from traffic is clear at these AURN sites. However, at Birmingham Adcocks Green (figure 4(c)) and Exeter Roadside (figure 4(d)) there is no change in NO<sub>2</sub> concentrations after lockdown. Furthermore, at Chilbolton Observatory (figure 4(e)) and Eastbourne (figure 4(f)) there has been an increase in NO<sub>2</sub> concentrations after

lockdown, corresponding to  $\Delta$  NO<sub>2</sub> Total of  $+36\%$  and  $+46\%$  respectively.

## 5.2. NO<sub>2</sub> concentration changes at individual AURN sites

Figure 5 shows the measured NO<sub>2</sub> concentrations, with a 24-hour moving average applied (blue) and model predictions for the same period (red) for 4 AURN sites. At all sites the models capture the NO<sub>2</sub> variability in the pre-lockdown period well ( $R^2 > 0.5$ ). In the post-lockdown period, the measured NO<sub>2</sub> concentrations are generally lower than the model predictions. Since the model predicts the NO<sub>2</sub> concentrations expected given no change in NO<sub>2</sub> emissions, this suggests that emissions of NO<sub>2</sub> have reduced

**Table 2.** Changes in NO<sub>2</sub> at individual AURN stations and averaged across sites with the same type. AURN site types are classified as Traffic (T) or background (BG) sites.  $\Delta$  NO<sub>2</sub> Total ( $\mu\text{gm}^{-3}$ ) is the total change in NO<sub>2</sub> concentrations between the post-lockdown (17/03/20 - 30/04/20) and pre-lockdown (01/02/20 - 16/03/20) period.  $\Delta$  NO<sub>2</sub> Total (%) is the change relative to a 5-year climatology.  $\Delta$  NO<sub>2</sub> Met is the percentage change attributed to changes in the meteorology.  $\Delta$  NO<sub>2</sub> Emission is the percentage change attributed to changes in emissions.  $\pm$  value is the standard error of the mean. R<sup>2</sup> is the coefficient of determination for each model for the 5-year training period (01/01/15 - 31/12/19).

Location	Site Type	$\Delta$ NO <sub>2</sub> Total ( $\mu\text{gm}^{-3}$ )	$\Delta$ NO <sub>2</sub> Total (%)	$\Delta$ NO <sub>2</sub> Met (%)	$\Delta$ NO <sub>2</sub> Emission (%)	Correlation (R <sup>2</sup> )
London Marylebone	Urban T	-36	-42	-8	-34	0.52
Glasgow Kerbside	Urban T	-20	-30	19	-49	0.54
Belfast Centre	Urban BG	-20	-71	-53	-19	0.42
Halford-yr-yrns	Urban T	-19	-26	8	-34	0.54
Birmingham Adcocks Green	Urban BG	0	-2	18	-20	0.55
Exeter Roadside	Urban T	0	0	33	-33	0.59
Reading New Town	Urban BG	2	6	40	-34	0.54
Chilbolton Observatory	Rural BG	6	36	23	13	0.60
Eastbourne	Urban BG	8	46	22	24	0.55
59 AURN sites	Urban T	-7 $\pm$ 1	-19 $\pm$ 2	8 $\pm$ 3	-27 $\pm$ 2	0.53
53 AURN sites	Urban BG	-4 $\pm$ 1	-14 $\pm$ 3	0 $\pm$ 3	-14 $\pm$ 2	0.48
13 AURN sites	Rural BG	1 $\pm$ 1	20 $\pm$ 6	20 $\pm$ 9	0 $\pm$ 7	0.41
142 AURN sites	All	-5 $\pm$ 1	-12 $\pm$ 2	6 $\pm$ 2	-18 $\pm$ 1	0.49

at all 4 sites. This is particularly evident at London Marylebone Road (figure 5(a)) and Glasgow Kerbside (figure 5(b)) where NO<sub>2</sub> emissions reduce by 34% and 49% respectively. At Birmingham Adcocks Green (figure 5(c)) the mean concentration did not change significantly from the pre- and post-lockdown period ( $< 1\mu\text{gm}^{-3}$ ). However, given no change in emissions, changes in the meteorology would have resulted in a change to NO<sub>2</sub> concentrations of +18%. Changes in the emissions caused a change in NO<sub>2</sub> concentration of -20%, therefore resulting in a negligible total change. Thus, despite the fact that there was little change in total NO<sub>2</sub> concentrations, emissions of primary NO<sub>2</sub> and secondary NO<sub>2</sub> precursors were still found to reduce as a result of the COVID-19 restrictions. Similarly, at Exeter Roadside (figure 5(d)) there is no change in the mean concentration between the pre-lockdown period and the post-lockdown period. However, changes in the meteorology would have resulted in an increase in NO<sub>2</sub> concentrations of +33%. This was offset by a reduction in emissions of -33%, resulting in no total change in NO<sub>2</sub> concentrations. Performing similar analysis at all 142 AURN sites in England shows that, given no change in emissions, the changes in meteorology between the pre- and post-lockdown period would have led to a mean increase in NO<sub>2</sub> concentrations of +6% (table 2). Conversely, changes in emissions would have led to a mean reduction in NO<sub>2</sub> concentrations of -18%, resulting in a mean total change of -12% (table 2).

### 5.3. Spatial variability in NO<sub>2</sub> concentrations changes

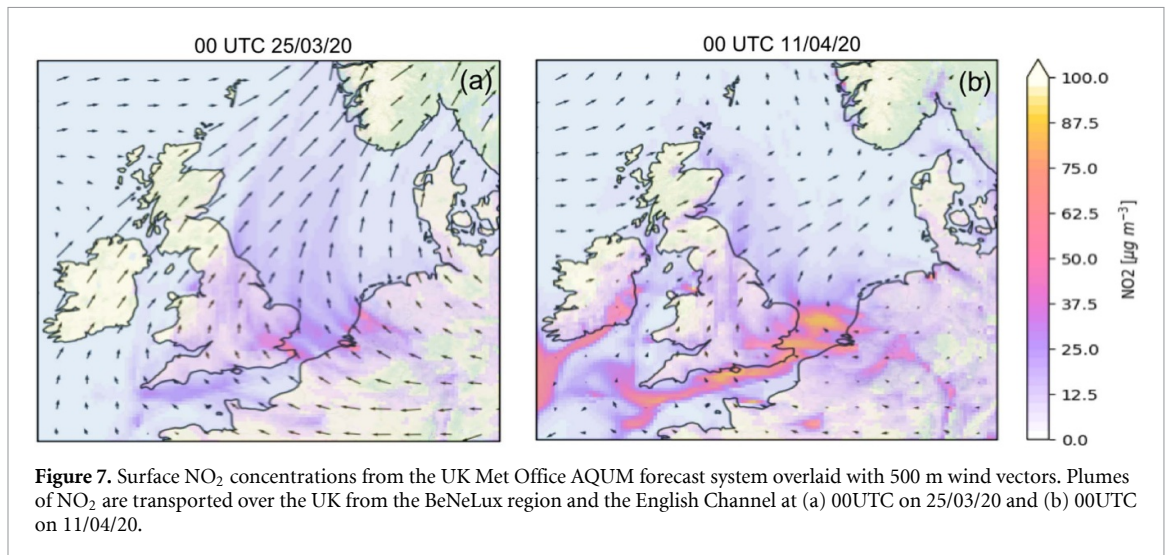

In this section the spatial variability in the total NO<sub>2</sub> concentration changes shown in figure 3(c) is discussed. Firstly, the north/south pattern in total

NO<sub>2</sub> concentration changes is investigated. Changes in the meteorology are found to be responsible for larger increases in NO<sub>2</sub> concentrations in the south of England and Wales than in central and northern parts of the UK (figure 6(a)). Changes in emissions are however more uniform over the UK (figure 6(b)). The meridional gradient in meteorological attributed changes in NO<sub>2</sub> is likely to be due to the advection of secondary NO<sub>2</sub> over the south of the UK by the predominantly south-easterly winds. This secondary NO<sub>2</sub> is produced over the English Channel and BeNeLux regions and transported towards the UK during periods dominated by high-pressure and easterly winds. Two examples of anticyclonic NO<sub>2</sub> transport during the post-lockdown period are shown in figures 7(a) and (b) with plumes of NO<sub>2</sub> being transported over the UK, particularly the south and east coast of England. According to Lamb weather type, between 17/03/20 and 30/04/20, 48% of the days were classed as anticyclonic, resulting in frequent regional transport of NO<sub>2</sub> from Europe to the UK in the post-lockdown period.

Secondly, within the north/south pattern in total NO<sub>2</sub> concentration changes there is some spatial variability. The largest increases associated with changes in the meteorology are seen at rural sites (20 $\pm$ 2%, table 2) at which the NO<sub>2</sub> measurements are more representative of large areas (1000 km<sup>2</sup>) and thus NO<sub>2</sub> concentrations are dominated by the regional advection of secondary NO<sub>2</sub> (Harrison and McCartney 1980). Conversely, mean changes in NO<sub>2</sub> concentrations at urban traffic and urban background sites (-27% and -14% respectively, table 2) are representative of more local areas (few km<sup>2</sup>) and are more influenced by local reductions in emissions of primary NO<sub>2</sub> and secondary NO<sub>2</sub> precursors (i.e. NO). The largest reduction in emissions are

**Figure 6.** Change in post- and pre-lockdown  $\text{NO}_2$  concentrations attributable to (a) changes in meteorology and (b) changes in emissions.

**Figure 7.** Surface  $\text{NO}_2$  concentrations from the UK Met Office AQUM forecast system overlaid with 500 m wind vectors. Plumes of  $\text{NO}_2$  are transported over the UK from the BeNeLux region and the English Channel at (a) 00UTC on 25/03/20 and (b) 00UTC on 11/04/20.

seen at urban traffic sites such as Bristol Temple Way ( $-59\%$ ), Oxford Centre ( $-45\%$ ) and Dumbar-ton ( $-43\%$ ). A few of the sites ( $< 10\%$ ) have small increases in  $\text{NO}_2$  emissions, however these are largely background sites where the absolute change in  $\text{NO}_2$  concentrations is small ( $< 5\mu\text{gm}^{-3}$ ).

## 6. Conclusions

The aim of this work is to investigate the spatial distribution of changes in  $\text{NO}_2$  concentration in the UK between the 6-weeks prior to COVID-19 travel restrictions (01/02/20 – 16/03/20, referred to as ‘pre-lockdown’) and the 6-weeks after travel restrictions were imposed (17/03/20 – 30/04/20, referred to as ‘post-lockdown’). The change of  $\text{NO}_2$  concentrations between the pre- and post-lockdown periods show an interesting north-south gradient. AURN stations in the north and middle of England measure a decrease in  $\text{NO}_2$  concentrations in the post-lockdown period

whereas stations in the south of England measure an increase in  $\text{NO}_2$  concentrations. The measured change in  $\text{NO}_2$  concentrations is separated into contributions due to changes in meteorology and emissions using statistical regression. The results show that, given no change in emissions, an increased frequency of easterlies during the post-lockdown period would have caused an increase in  $\text{NO}_2$  concentrations, particularly in the south of England and parts of Wales. Conversely, a reduction in  $\text{NO}_2$  emissions caused a decrease in  $\text{NO}_2$  concentrations at most urban traffic and urban background AURN sites. In the north and middle of England the decrease in  $\text{NO}_2$  concentrations due to reduced emissions is greater than the increase due to change in the meteorology resulting in an observed decrease in  $\text{NO}_2$  concentrations. In the south of England, the reverse is true resulting in an observed increase in  $\text{NO}_2$  concentrations. Thus,  $\text{NO}_2$  emissions have reduced over the majority of the UK but the analysis shows that it is important to

consider both meteorological and emissions changes in order to explain the observed NO<sub>2</sub> concentration changes.

The restrictions put in place during lockdown provide a unique experiment in which the response of air quality to implemented strategies can be determined. Short-term clean air mitigation strategies have been studied previously, such as those in place for the 2008 Beijing Olympics or the result of economic recession (Castellanos and Boersma 2012). Since current lockdown measures are not sustainable, it is predicted that NO<sub>2</sub> concentrations will return to pre-COVID levels unless we use lessons learnt from the lockdown to make changes (El Zowalaty and Järhult 2020). Any positive environmental effects are likely mostly temporary, but may serve as an example that changes in our way of life can have prompt positive effects for the environment and demonstrate the usefulness of travel-reducing measures such as those proposed by Carslaw and Bevers (2002).

## Acknowledgment

We would like to thank Kaja Milczewska (University of Reading), Paul Agnew (Met Office) and Matthew Hort (Met Office) for useful discussions on this work.

## Data availability

The air quality data that support the findings of this study are openly available at the following URL: [uk-air.defra.gov.uk/networks/network-info?view=aurun](http://uk-air.defra.gov.uk/networks/network-info?view=aurun).
