23 [Capsule Summary](#)

24 During austral spring 2019 the Antarctic stratosphere experienced record-breaking warming
25 and a near-record polar vortex weakening, resulting in predictable extreme climate conditions
26 throughout the Southern Hemisphere through December 2019.

27

28 Abstract

29 This study offers an overview of the low-frequency (i.e., monthly to seasonal) evolution,
30 dynamics, predictability, and surface impacts of a rare Southern Hemisphere (SH)
31 stratospheric warming that occurred in austral spring 2019. Between late August to mid-
32 September 2019, the stratospheric circumpolar westerly jet weakened rapidly, and Antarctic
33 stratospheric temperatures rose dramatically. The deceleration of the vortex at 10 hPa was as
34 drastic as that of the first ever observed major sudden stratospheric warming in the SH during
35 2002, while the mean Antarctic warming over the course of spring 2019 broke the previous
36 record of 2002 by ~50% in the mid-stratosphere. This event was preceded by a poleward shift
37 of the SH polar night jet in the uppermost stratosphere in early winter, which was then
38 followed by record-strong planetary wave-one activity propagating upward from the
39 troposphere in August that acted to dramatically weaken the polar vortex throughout the
40 depth of the stratosphere. The weakened vortex winds and elevated temperatures moved
41 downward to the surface from mid-October to December, promoting a record strong swing of
42 the Southern Annular Mode (SAM) to its negative phase. This record-negative SAM
43 appeared to be a primary driver of the extreme hot and dry conditions over subtropical
44 eastern Australia that accompanied the severe wildfires that occurred in late spring 2019.
45 State-of-the-art dynamical seasonal forecast systems skilfully predicted the significant vortex
46 weakening of spring 2019 and subsequent development of negative SAM from as early as
47 late July.

48 Introduction

49 Sudden stratospheric warming events (SSWs) are characterized by dramatic warming and
50 weakening of the stratospheric polar vortex. SSWs have a profound impact on stratospheric
51 circulation and chemical composition and can drive sustained anomalies in surface weather,
52 altering the occurrence of weather and climate extremes (e.g., Kidston et al. 2015; King et al.
53 2019; Lim et al. 2019), thus serving as an important source of long-range predictability (e.g.,
54 Baldwin and Dunkerton 2001; Domeisen et al. 2020). Major SSWs, which are defined by a
55 reversal of the climatological westerly vortex in the mid-stratosphere followed by a recovery
56 (Charlton and Polvani 2007; Butler et al. 2015), occur every 1-2 years on average in the
57 Northern Hemisphere (NH), but are extremely rare in the Southern Hemisphere (SH): only
58 one major SSW has been observed in the SH over the past ~60 years, which occurred during
59 late September 2002 (e.g., Baldwin et al. 2003; Dowdy et al. 2004; Nishii and Nakamura
60 2004; Shepherd et al. 2005).

61 The 2002 major SSW, which was a vortex-splitting event, occurred with
62 extraordinarily strong wave forcing from the troposphere throughout the preceding austral
63 winter and the associated contraction of the polar vortex from late winter (e.g., Harnik et al.
64 2005; Newman and Nash 2005; Scaife et al. 2005). It then dramatically developed over 10
65 days from 17 September with upper stratospheric preconditioning (e.g., Newman and Nash
66 2005; Scaife et al. 2005) and resonant amplification of wave forcing within the stratosphere
67 (Esler et al. 2006), and the wind reversal occurred during 25-30 September. During the 2002
68 SSW, the stratospheric jet at 10 hPa weakened by 80 ms^{-1} and the Antarctic polar cap (the
69 area mean over $60\text{-}90^\circ\text{S}$) warmed by 32 K at 30 hPa from September 17 to 27 (NASA Ozone
70 Watch; <https://ozonewatch.gsfc.nasa.gov/>). These extreme wind and temperature anomalies
71 subsequently coupled downward, leading to the record strong low polarity (negative) index of

72 the Southern Annular Mode (SAM; Thompson and Wallace 2000) and associated surface
73 climate extremes in the following spring months (Thompson et al. 2005; Hendon et al. 2020).

74 Beginning in late August 2019, the SH stratospheric polar vortex experienced radical
75 warming and weakening, which was of comparable magnitude to what occurred during 2002,
76 and was displaced from the South Pole (rather than split). Lim et al. (2020) and subsequent
77 studies (e.g., Eswaraiah et al. 2020; Rao et al. 2020; Shen et al. 2020) reported that the
78 stratospheric jet at 10 hPa at 60°S weakened by 80 ms⁻¹, and the polar cap warmed by 35 K at
79 30 hPa during the three weeks following 25 August 2019, setting records for the highest polar
80 cap temperature and weakest westerly jet in the mid to upper stratosphere in September.

81 The weakened vortex in September then coupled downward to the troposphere from
82 mid-October to December 2019, with an extraordinarily persistent equatorward shift of the
83 tropospheric eddy-driven westerly jet and a concomitant increase of surface pressure in the
84 polar region and a decrease in the SH midlatitudes. Together these changes characterize a
85 swing to the negative phase of the SAM (hereafter, referred to as negative SAM), which
86 typically follows anomalous springtime weakening of the SH polar vortex, such as those
87 observed in 1988 and 2002 (Thompson et al. 2005; Seviour et al. 2014; Byrne and Shepherd
88 2018; Lim et al. 2019). The negative SAM in late spring 2019 was record-strong for the
89 season and played a significant role in exacerbating the pre-existing hot and dry conditions
90 over Australia, which were conducive to the devastating wildfires (known as bushfires in
91 Australia) that ensued along the central east coast (Phillips and Nogrady 2020). It also
92 contributed to below-average rainfall in northeastern Brazil and eastern South Africa, and
93 above-average rainfall in southeastern Brazil, western Patagonia and southernmost New
94 Zealand during late October through December 2019 (Lim et al. 2020).

95 Recent studies have already unraveled some key mechanisms that triggered the SSW
96 in mid-September 2019 on daily to weekly timescales (Eswaraiah et al. 2020; Rao et al. 2020;

97 Shen et al. 2020) and have identified significant impacts of this event on the different
98 atmospheric layers and regions (Yamazaki et al. 2020; Noguchi et al. 2020; Anstey et al.
99 2020; Wargan et al. 2020). Here we concentrate on the low-frequency (i.e., spring season)
100 manifestation of the 2019 SSW, which is, hereafter, referred to as springtime stratospheric
101 polar vortex (SPV) weakening. We show that the origin of this event can be traced back to
102 changes in the polar night jet (PNJ) at the stratopause as early as June 2019 and whose
103 surface impacts were felt through December 2019. We also explore the long-lead
104 predictability of the springtime SPV weakening event using both inferences from lagged
105 statistical relationships based on historical data and coupled model seasonal forecast systems
106 (as opposed to a deterministic prediction of the precise timing of the SSW) and of the
107 sustained surface impacts into austral late spring/early summer 2019. This focus on the
108 monthly to seasonal timescale evolution of the stratospheric circulation associated with the
109 vortex weakening event and its sustained coupling downward to the surface highlights that
110 springtime SPV variability and associated preconditioning processes are a potential source of
111 predictability of surface climate with lead times much longer than associated with prediction
112 of the abrupt SSW.

113 For the observational analysis, we have used the Japanese Reanalysis-55 dataset
114 (JRA-55; Kobayashi et al. 2015) and Global Precipitation Climatology Project (GPCP)
115 precipitation version 2.3 dataset (Adler et al. 2018) for 1979-2019. We computed anomalies
116 for 2019 using the climatology of 1979-2018. For the SPV index and other climate indices,
117 we normalized the index anomalies by their standard deviations (σ) obtained from the
118 climatological 40 year data. We also analyzed the Australian Water Availability Project
119 (AWAP) gridded analyses (Jones et al. 2009) of Australian temperature and rainfall and a

120 gridded dataset of the McArthur forest fire danger index¹ (Dowdy 2018) to examine the
121 impact of the 2019 SPV weakening on Australian climate in late 2019.

122 The coupled model seasonal hindcasts for 1990-2012 and real-time forecasts for 2019
123 were produced from the operational systems of the Australian Bureau of Meteorology (BoM
124 ACCESS-S1; Hudson et al. 2017), the European Centre for Medium-Range Weather
125 Forecasts (ECMWF-SEAS5; Johnson et al. 2018), the Japan Meteorological Agency
126 (JMA/MRI-CPS2; Takaya et al. 2018), NASA (GEOS-S2S-2; Molod et al. 2020), and the
127 UK Met Office (UKMO GloSea5; MacLachlan et al. 2015). Details of the forecast systems
128 and configurations are described in Table 1.

129 [Setting new records](#)

130 The PNJ, the Antarctic temperatures, and the SAM were all severely disrupted in association
131 with the 2019 SPV weakening. Figure 1a shows Antarctic circumpolar zonal wind anomalies
132 at 60°S (shading) for 1 June to 31 December 2019 (1000 hPa to 1 hPa) superimposed on the
133 climatology (contours). The sudden and massive vortex weakening in the upper stratosphere
134 began in late August and then extended downward into the troposphere from October through
135 the end of December, manifested as persistent period of strong negative SAM (Fig. 1b),
136 which is monitored with the CPC AAO index (available at
137 https://www.cpc.ncep.noaa.gov/products/precip/CWlink/daily_ao_index/ao/ao.shtml;

¹ The McArthur Forest Fire Danger Index (FFDI) was obtained from a dataset as described by Dowdy (2018), based on a gridded analysis of observations at 0.05 degrees in both latitude and longitude throughout Australia. The FFDI is calculated as an exponential function combining relative humidity, temperature and wind speed as well as a drought factor based on a measure of fuel dryness calculated from antecedent rainfall and temperature. The FFDI has been shown to exhibit predictability on seasonal timescales (Bett et al. 2020), but it is used here as a useful way of combining various weather factors known to influence fire danger and for providing broad-scale guidance on climatological features including its relationship to large-scale atmospheric and oceanic modes of variability such as the SAM, stratospheric polar vortex and El Niño-Southern Oscillation.

138 Thompson and Wallace 2000). Concomitant with the vortex weakening, the polar cap
139 temperature rapidly increased in the upper to mid stratosphere and then stayed significantly
140 warmer than normal in the lower stratosphere through December (Fig. 1c). Consistent with
141 thermal-wind balance, the maximum warm anomalies sit below the maximum easterly
142 anomalies. By comparing to the climatological zonal wind, the springtime SPV weakening of
143 2019 can be viewed as an accelerated march of the seasonal cycle of the SH stratospheric
144 circulation, resulting in an earlier-than-normal breakdown of the winter vortex (e.g., Shiotani
145 et al. 1993; Taguchi and Yoden 2002; Hio and Yoden 2005; Byrne and Shepherd 2018).

146 Although the 2019 SSW did not experience a zonal wind reversal at 60°S and 10 hPa
147 to qualify as a major SSW (e.g., Butler et al. 2015), many other measures point to this event
148 being of record strength, especially when viewed on longer (monthly to seasonal) timescales.
149 For example, the austral springtime mean (September-November; SON) zonal-mean zonal
150 wind ($[U]$) at 60°S and 1 hPa was the weakest on record by a big margin over the previous
151 records (-3σ compared to -2σ in 1988 and 2002) (e.g., Eswaraiah et al. 2020); and the
152 weakening of $[U]$ at 60°S and 10 hPa was on a par with 2002, with a magnitude of -3.0σ
153 (Fig. 2b). Similarly, the amplitude of the leading empirical orthogonal function (EOF) of
154 Antarctic polar cap geopotential height anomalies at 30 hPa, which depicts the earlier/later
155 breakdown of the SH stratospheric polar vortex (Byrne and Shepherd 2018), was 2.3σ in both
156 2002 and 2019 (Supplementary Figs. S1a,b). Likewise, the leading time-height EOF of
157 Antarctic circumpolar zonal wind, which also captures the variability of the canonical life
158 cycle of the SH stratospheric vortex weakening and its downward coupling to the troposphere
159 that typically evolves from early winter at the stratopause to summer at the surface (Lim et al.
160 2018), exhibited the record magnitude of 2.5σ in 2002 and 2019 (Supplementary Figs. S1c,d).

161 There were two records related to the SPV weakening: springtime polar stratospheric
162 temperatures and ozone concentrations were both at record highs – resulting in a very small

163 Antarctic ozone hole. The record high temperatures were especially evident in the mid-
164 stratosphere (30 hPa) where the polar temperature anomaly was about 50% higher than in
165 2002 (Fig. 2c). Typically, Antarctic polar cap ozone increases as the SH stratospheric polar
166 vortex weakens and warms (e.g., Stolarski et al. 2005; Keeble et al. 2014; Seviour et al.
167 2014). The strengthened Brewer-Dobson circulation associated with the 2019 SPV
168 weakening (Noguchi et al. 2020) transported mid-stratospheric ozone from the midlatitudes
169 into the polar region, while also developing an enhanced downward circulation that warmed
170 the polar lower stratosphere (Wargan et al. 2020). This warming curtailed the typical chlorine
171 and bromine catalytic ozone loss processes that cause the ozone hole. The polar cap total
172 column ozone concentration in SON 2019 was the highest on record since 1979 (Fig. 2d)
173 primarily due to the SPV weakening (Wargan et al. 2020).

174 Despite the extraordinarily early start of the 2019 SSW in late August, the wind and
175 temperature anomalies did not couple down to the troposphere until mid-October. However,
176 once the stratosphere-troposphere coupling occurred, the resultant SAM index averaged over
177 October-December was the most strongly negative on record for that season (Fig. 2e), which
178 is consistent with a strong correlation between the October-December SAM index (Fig. 2c)
179 and the springtime SPV index (SPVI; defined here as $[U]$ at 60°S and 10 hPa averaged for
180 the SON season (Seviour et al. 2014); Fig. 2b) over 1979-2018 ($r \sim 0.66$).

181 Dynamical processes for the 2019 stratospheric vortex weakening

182 Before the drastic weakening of the polar vortex in September 2019, the PNJ at the
183 stratopause first shifted poleward during early austral winter (June-July), which is likely due
184 to increased wave forcing in early winter (e.g. Kodera and Kuroda 2002). The evolution of
185 the 2019 vortex weakening and a comparison to historically observed SH springtime SPV
186 events are shown in Figure 3. The right-hand column displays the 2019 evolution of zonal-
187 mean zonal wind anomalies ($[U]$) at 1 hPa (near the stratopause), 10 hPa (mid-stratosphere)

188 and 100 hPa (lower stratosphere) as a function of calendar month. The left-hand column
189 displays the same fields but derived from the regression onto the SPVI displayed in Fig. 2b.
190 The regression coefficient patterns were obtained using data for the period 1979-2018, and
191 the syntheses for 2019 were obtained by multiplying the regression coefficients by the 2019
192 value of the SPVI to show the evolution of [U]' at these different levels that was expected
193 from the 2019 SPV weakening in spring (see details in Supplemental Material).

194 For both the synthesized and observed anomalies of 2019, the development of easterly
195 anomalies in the mid and lower stratospheric polar vortex from September onward can be
196 traced back to a poleward shift (i.e., a meridional dipole anomaly) of the PNJ at 1 hPa during
197 early winter (Figs. 3a,b). This meridional dipole anomaly in the upper stratospheric westerlies
198 peaks in July and then gradually moves poleward through August in conjunction with the
199 seasonal poleward shift of the jet from winter to spring (e.g., Kodera and Kuroda 2002; Byrne
200 and Shepherd 2018). Beginning in September, the upper stratospheric wind anomaly takes the
201 form of a monopole weakening of the vortex that extends from 30°S to the pole. This rapid
202 latitudinal expansion of the easterly anomalies in the upper stratosphere in September,
203 reflecting the sustained effects of a weakened vortex, concurs with the appearance of easterly
204 anomalies in the mid to lower stratosphere that then persist through at least December (Figs.
205 3c-f).

206 We note that springtime weakening of the SH polar vortex coincides with easterly
207 anomalies in the low latitudes equatorward of 10°S at 10 hPa in both the canonical
208 development derived from regression and in the 2019 anomalies (Figs. 3c,d). The tropical
209 easterly anomalies at 10 hPa are a signal accompanying the westerly phase of the quasi-
210 biennial oscillation (QBO) defined at 30-50 hPa (e.g., Anstey et al. 2010; Shen et al. 2020;
211 for the QBO in 2019, see https://acd-ext.gsfc.nasa.gov/Data_services/met/qbo/qbo.html).
212 Tropical stratospheric winds could potentially alter wave propagation characteristics and/or

213 the stratospheric residual mean circulation in ways that affect the polar vortex (Holton and
214 Tan 1980; Baldwin et al. 2001; Anstey and Shepherd 2014; Byrne and Shepherd 2018; Gray
215 et al. 2020). Given the statistically significant connection between the easterly signal of the
216 QBO in May and a poleward shift of the westerly jet in the subsequent winter months at 10
217 hPa (Fig. 3c), an in-depth investigation is warranted for the influence of the QBO related
218 mid-stratospheric easterlies on the different stages of the polar vortex evolution during 2019
219 although Shen et al. (2020) briefly noted that the tropical easterly anomalies at 10 hPa
220 associated with the QBO were unlikely to be a direct cause of the 2019 SSW. On the other
221 hand, Anstey et al. (2020) suggest that the 2019 SSW impacted the QBO and its
222 predictability by significantly disrupting the downward propagation of the tropical easterly
223 anomalies to the lower stratosphere.

224 The preceding poleward shift of the PNJ during austral winter for both the historical
225 development of springtime vortex weakening and the 2019 event is maintained by a similar
226 dipole pattern of anomalous meridional eddy momentum flux convergence in the upper
227 stratosphere (Figs. 4a,b). Anomalous upward flux of wave activity from the troposphere into
228 the stratosphere, as indicated by the poleward eddy heat flux² at 100 hPa, develops over 50°-
229 70°S from July and peaks in September (Matsuno 1970; Shiotani et al. 1993; Kuroda and
230 Kodera 1998; Newman et al. 2001; Hio and Yoden 2005) (Figs. 4c,d).

231 The increased westerlies at 1 hPa (Fig. 3a) and associated increased upward and
232 equatorward propagating wave activities in the lower and upper stratosphere, respectively
233 (Figs. 4c and 4a), all appear on the poleward sides of their climatological maxima during July
234 and August. This is consistent with the concept that poleward movement of the winter PNJ,
235 which happens when Rossby waves break in the subtropical surf zone, acting to sharpen the

² The poleward eddy heat flux represents the upward flux of wave activity (Newman and Nash 2005). The poleward heat flux is negatively signed in the SH (i.e., northward heat flux being positive).

236 potential vorticity gradient and causing the polar vortex to shrink towards the pole, may focus
237 upward propagating wave activity into the polar cap, subsequently acting to weaken the
238 vortex (McIntyre and Palmer 1983; Kodera and Kuroda 2002; Harnik et al. 2005; Albers and
239 Birner 2014; Lawrence and Manney 2020 and references therein). The poleward heat flux
240 anomalies at 100 hPa increase dramatically from July to October (Fig. 4c), and the
241 convergence of this heat flux in the vertical exerts the necessary easterly forcing to weaken
242 the vortex from August onward (Supplementary Fig. S2). The 2019 anomalies appear to
243 closely follow the canonical evolution of the upper stratospheric winds and planetary wave
244 activity for springtime polar vortex weakening, but the poleward heat flux anomalies at 100
245 hPa were extraordinarily strong in August and September 2019 (Fig. 4d), which was
246 consistent with the resultant record weakening of the polar vortex.

247 More details of the increased poleward heat flux during 2019 are provided in Figure
248 5a, which displays the standardized amplitudes of the wave-1 poleward heat flux anomalies
249 averaged over 45-75°S at different vertical levels during May-December 2019 (Jucker 2016;
250 Birner and Albers 2017). We limit our interest to the wave-1 heat flux as it was the most
251 dominant component in the wave forcing for the 2019 SSW (Rao et al. 2020; Shen et al.
252 2020), although there was a substantial positive contribution of the wave-2 heat flux in July
253 (Supplementary Fig. S3). The initial wave-1 poleward heat flux increases in June were
254 confined to the mid and upper stratosphere, consistent with the poleward contraction of the
255 PNJ as discussed earlier. Subsequently in August and September 2019, extraordinarily strong
256 heat flux anomalies ($< -3\sigma$) developed throughout the troposphere and stratosphere (e.g.,
257 Milinevsky et al. 2019). This wave-1 heat flux event of August 2019 was the 2nd strongest in
258 the lower troposphere (after 1988) and the strongest at 100 hPa since 1979 (Supplementary
259 Fig. S4).

260 Although a growing body of research shows that SSWs can occur without the
261 anomalous upward wave activity flux emanating from the troposphere (e.g., Scott and
262 Polvani 2004; Esler and Scott 2005; Jucker 2016; Birner and Albers 2017), an indication of
263 the tropospheric source of the enhanced upward injection of wave activity (i.e., enhanced
264 poleward heat flux) in late winter 2019 is provided by the August-mean eddy geopotential
265 height averaged over 45-75°S (Fig. 5b) and 700 hPa geopotential height anomalies (Z700)
266 (Fig. 5c). The observed SH Z700 anomalies in August 2019 are characterized by a primary
267 anticyclonic anomaly over the Bellingshausen-Amundsen Seas and a secondary anticyclonic
268 anomaly in the Southern Indian Ocean south of Australia with two cyclonic anomaly centers
269 in-between. This pattern strongly projects onto the Z700 anomaly patterns associated with the
270 increase of the wave-1 poleward heat flux at 700 hPa and, to a less degree, at 100 hPa
271 (Supplementary Fig. S5). The eddy geopotential height pattern of 2019 shows that this lower
272 tropospheric wave pattern propagates upward with a westward tilt, significantly amplifying in
273 the upper stratosphere (Fig. 5b), suggesting that the anomalous tropospheric wave pattern in
274 2019 was conducive to vertical wave propagation. Rao et al. (2020) and Shen et al. (2020)
275 show that the upward propagating wave-1 activity further increased in September, playing a
276 key role in the onset of the SSW.

277 Our preliminary investigation to find possible sources of this extraordinary increase of
278 the wave-1 poleward heat flux hints that convection anomalies over the tropical-subtropical
279 Indian and western Pacific Oceans could have acted as the sources of the teleconnection that
280 promoted the August lower tropospheric circulation anomaly (Supplementary Fig. S6). More
281 sophisticated wave analysis and/or carefully designed dynamical modelling experiments
282 would help further elucidate possible tropical influences on the poleward heat fluxes and
283 resultant SH spring vortex variations, which is beyond the scope of this study.

284 Impact on the SH regional climate

285 The 2019 stratospheric vortex weakening signal descended to the surface from mid-October
286 through December (Fig. 1), setting a new record for negative SAM for that season (Fig. 2e).
287 Negative SAM is characterized by equatorward shifts of the tropospheric eddy-driven
288 westerly jet and associated midlatitude storm track, therefore bringing wet and cold
289 conditions to western Patagonia and southeast South America (SA), western Tasmania, and
290 southern New Zealand and dry westerly winds over southern portions of Australia in the
291 October to December season (OND) as well as in austral summer (e.g., Gillett et al. 2006;
292 Lim et al. 2018; Garreaud 2018). Additionally, negative SAM is accompanied by an
293 equatorward shift of the descending branch of the SH Hadley cell in austral warm seasons
294 (e.g., Kang et al. 2011; Ceppi and Hartmann 2013; Hendon et al. 2014), therefore resulting in
295 increased downward motion and reduced cloudiness in the SH subtropics and associated dry
296 and warm conditions, which are most prominent over eastern Australia (Lim et al. 2018,
297 2019).

298 The SH horizontal and vertical circulation anomalies of OND 2019 closely followed
299 the canonical responses to the springtime SPV weakening, as depicted by regression onto the
300 SPVI (Fig. 6). Although the observed pressure anomalies depict negative SAM (Fig. 6b),
301 they are less zonally symmetric than the canonical response to vortex weakening especially
302 over the central and eastern portions of the South Pacific (Fig. 6a). This feature is largely
303 explained by the presence of Central Pacific (CP) El Niño and the extraordinarily strong
304 positive Indian Ocean dipole mode (IOD) (Supplementary Figs. S7a-c), which are monitored

305 by the El Nino Modoki Index (EMI³; Ashok et al. 2007) and the Dipole Mode Index (DMI⁴;
306 Saji et al. 1999) (Supplementary Fig. S8), respectively. Both CP El Nino and IOD promote
307 Rossby wave trains that propagate toward the southeast Pacific, thereby contributing to
308 zonally asymmetric circulations in the SH extratropics (Supplementary Figs. S7d-f; e.g.,
309 Ashok et al. 2007; Cai et al. 2011). Consequently, the large-scale circulation anomalies over
310 the southern Atlantic and far eastern Pacific were weaker than those typically observed
311 during the springtime SPV weakening and negative SAM, which led to only moderate wet
312 anomalies in western Patagonia and cold anomalies in the southern tip of SA and around the
313 Antarctic Peninsula (Fig. 6 right panels). In contrast, a dipole of precipitation and temperature
314 anomalies along eastern SA was prominent in late spring 2019: eastern Brazil was
315 significantly warmer and drier than normal with significantly enhanced downward motion
316 and reduced cloud cover, whereas the opposite conditions occurred in Uruguay and parts of
317 Argentina (Fig. 6d, Supplementary Fig. S9b). These dipole patterns are similar to those
318 associated with the springtime SPV weakening and negative SAM (Fig. 6c, Supplementary
319 Fig. S9a) but much more intense.

320 As broadcast world-wide, eastern Australia suffered from extreme hot and dry
321 conditions and resultant severe wildfires during OND 2019 (e.g., Phillips and Nogrady 2020).
322 Significantly enhanced downward motion, clearer skies, higher temperatures, and lower
323 rainfall over eastern Australia were highly consistent with the anomalies expected to occur
324 during SPV weakening and negative SAM (Fig. 6 and Supplementary Fig. S9; Lim et al.
325 2019). Furthermore, the positive IOD in OND 2019 was record strong for the season as

³ $EMI = \overline{SST}_{cp} - 0.5 * (\overline{SST}_{ep} + \overline{SST}_{wp})$, where cp denotes tropical central Pacific (10°S-10°N, 165-220°E), ep denotes tropical eastern Pacific (15°S-5°N, 250-290°E), and wp denotes tropical western Pacific (10°S-20°N, 125-145°E). The overbar represents the area average.

⁴ $DMI = \overline{SST}(10^{\circ}S - 10^{\circ}N, 50 - 70^{\circ}E) - \overline{SST}(0 - 10^{\circ}S, 90 - 110^{\circ}E)$ where the overbar denotes the area average.

326 evidenced by the DMI being greater than 3σ , and CP El Nino was strong as well, as judged
327 by the EMI being 1σ in NOAA OI v2 SST data (Reynolds et al. 2002) (which was combined
328 with Hurrell et al. (2008) SST data for 1979-1981 in our analysis) (Supplementary Fig. S8).
329 These anomalous SST conditions are well-known drivers of hot and dry conditions over
330 Australia in its spring season (e.g., Saji and Yamagata 2003; Wang and Hendon 2007; Cai et
331 al. 2011), providing long-lead predictability. All these extreme large-scale conditions
332 impacted Australian late spring climate on top of its on-going long-term warming trend,
333 much of which is thought to be anthropogenically driven (Reisinger et al. 2014), and the
334 multi-year drought that had begun in 2017
335 (<http://www.bom.gov.au/climate/drought/knowledge-centre/previous-droughts.shtml>).
336 Together, they resulted in extreme conditions for wildfire occurrence across the country.

337 To better understand the relative roles of the stratospheric polar vortex weakening
338 (and associated negative SAM), CP El Nino, the positive IOD, and the linear long-term trend
339 for the late spring extreme climate of Australia in 2019, we have synthesized the Australian
340 daily maximum temperature (Tmax), rainfall, and forest fire danger index (FFDI) for late
341 spring (OND) 2019, based on multiple linear regression. For this “storyline” approach
342 (Shepherd 2019), we used four predictors – the de-trended EMI and DMI for OND, the de-
343 trended SPVI, and time to capture any trend since 1979⁵. Figure 7 shows that all four
344 predictors significantly contributed to the hot, dry, and fire-prone conditions over different
345 parts of Australia. CP El Nino contributed to drier conditions country-wide but especially in
346 the north (Figs. 7a,g,m) while the positive IOD contributed to intense hot, dry, and dangerous
347 fire weather conditions in the southeast (Figs. 7b,h,n). The linear trend since 1979 contributed

⁵ The EMI and DMI of the October-December mean and the SPVI of September-November mean do not have any significant trends over the study period 1979-2018, and they are not significantly correlated to one another ($p > 0.1$).

348 more modestly to the warming in the southern half of the country while making the northwest
349 wetter (Figs. 7d,j,p). The springtime SPV weakening and associated negative SAM appears to
350 have played the most prominent role in the hot, dry, and fire-conducive weather conditions in
351 subtropical eastern Australia (Figs. 7c,i,o), especially along the eastern seaboard of southern
352 Queensland and New South Wales, where severe wildfires occurred from October to
353 December⁶. For the FFDI averaged east of 150°E (the dashed vertical line in Figs. 7m-r), the
354 SPV weakening contributed 43% (28%) to the reconstructed (observed) anomaly, while CP
355 El Nino, the positive IOD and the linear trend contributed 21%, 24%, and 12% (14%, 16%,
356 and 8%) to the reconstruction (observation), respectively.

357 Although the reconstructed Tmax, rainfall, and fire danger index reasonably well
358 capture the observed conditions in the east (Fig. 7 right two columns), the hot and dry and
359 forest fire danger anomalies in the north and the west of the country far exceeded the
360 reconstruction based on these four large-scale oceanic and atmospheric drivers over the last
361 40 year period. It is important to note that apart from the linear trend shown in Fig. 7, it is
362 challenging to disentangle more complicated potential influences of multi-year to decadal
363 variabilities and climate change on the Australian climate extremes and wildfire risks
364 observed in late spring 2019, which require data of longer records and/or carefully designed
365 dynamical model experiments. Despite this inherent limitation of our simple statistical
366 analysis method, it still provides valuable insight that more than half of the observed forest
367 fire danger risk over the fire-struck region in the southeast could be explained by the
368 internally-driven dynamical circulation anomalies, and about half of that circulation-driven
369 risk could be explained by the record strong stratospheric warming event.

⁶ <https://www.industry.gov.au/data-and-publications/estimating-greenhouse-gas-emissions-from-bushfires-in-australias-temperate-forests-focus-on-2019-20>. Figure 5 in the document shows the areas significantly affected by the bushfires in July 2019 to January 2020. See also Phillips and Nogrady (2020).

370 Prediction of the 2019 springtime vortex weakening and its impact

371 To see how well the 2019 springtime SPV weakening and its impact on the SH
372 surface climate were predicted, we first consider a multiple linear regression model to predict
373 the SPVI. We use as predictors the PNJ at the stratopause (i.e., [U]' at 60°S, 1 hPa) in June-
374 July and the partial poleward heat flux anomaly at 100 hPa in July-August, which is
375 independent of the June-July PNJ by regressing out the covarying component with the PNJ
376 from the heat flux anomaly⁷ (Fig. 8). Based on the data over 1979-2018, the correlation of the
377 predicted SPVI using the multiple linear regression model with the observed SPVI is 0.73
378 (using leave-one-year-out cross-validation⁸; Wilks 2006). This statistical model skilfully
379 captures the magnitude of the 2019 event to be comparable to those of 2002 and 1988, the
380 latter being another strong stratospheric warming event with a vortex displacement but
381 without a wind reversal. A linear regression model with a single predictor, either the June-
382 July PNJ or the July-August 100 hPa poleward heat flux, provides prediction skill of 0.63.
383 However, the June-July PNJ alone underestimates the magnitudes of the 2019 and 1988
384 events (Fig. 8), while the July-August poleward heat flux alone underestimates the magnitude
385 of the 2002 event. Therefore, this statistical model confirms that both the preconditioning
386 provided by the poleward shift of the PNJ in early winter and subsequent anomalous wave
387 activity flux from the troposphere into the stratosphere in late winter were important for the
388 development of sustained weakening of the SH polar vortex in spring.

389 Predictability of SPV variability is further assessed using state-of-the-art dynamical
390 seasonal forecast systems (Table 1). Our skill assessment is based on hindcasts over 1990-
391 2012 (with a simple bias correction of using each model's anomalies relative to its

⁷ June-July PNJ at 1 hPa and July-August poleward heat flux at 100 hPa is correlated by 0.48. While this covariation is naturally accounted for by multiple linear regression (Panofsky and Brier 1963), we have used the partial poleward heat flux at 100 hPa of July-August to assure the independence of the predictors.

⁸ Similar skill is obtained with cross-validation processes leaving 5 or 10 years out.

392 climatology as a function of forecast lead time). Using the hindcasts, the SPVI is predictable,
393 as judged by temporal correlation skill (r) being 0.42, which is statistically significant at the
394 5% level (assessed by a two-tailed Student t-test with 23 independent forecast samples) from
395 as early as 1 July; and is skilfully predictable ($r > 0.6$) from early August (Fig. 9a; See also
396 Seviour et al. 2014, Byrne et al. 2019 and Hendon et al. 2020).

397 For the 2019 springtime SPV, the JMA, UKMO and ECMWF systems started
398 showing a sign of the weakening for forecasts initialized at the beginning of July (Fig. 9b).
399 Most of the systems predicted a substantially weaker vortex ($< -1\sigma$) for initializations in late
400 July and an extraordinary weakening ($< -2\sigma$) for initializations in late August, although there
401 was a drop in predictability in early to mid August. From the time when the vortex started its
402 sudden weakening and warming in the observations (i.e., late August to early September), the
403 BoM and UKMO systems, which are based on the same model, overpredicted the vortex
404 weakening and the ECMWF system underpredicted it relative to their standard deviations,
405 while NASA and JMA made skillful forecasts for it (Fig. 9b). In comparison, hindcast
406 predictions for the 2002 spring vortex weakening using the same systems show a similar lead
407 time dependence with an outstanding performance of the one-member NASA system
408 initialized in mid to late July, which then deteriorates in early-mid August before recovering
409 in late August (Fig. 9c).

410 An interesting aspect in Figure 9 is that predictions for the amplitude of the vortex
411 weakening varied by initialization dates only a few days apart for both 2002 and 2019, which
412 highlights the benefit of multiple forecast initialization times during a month and large
413 ensemble sizes to best capture the strength of the SH stratospheric polar vortex. The sharp
414 improvement in the model performance in predicting the strength of the 2019 springtime
415 vortex weakening for forecasts initialized closer to the event suggests that predictability of
416 the actual onset of the sudden warming and subsequent evolution of the polar vortex anomaly

417 throughout spring may be limited by the unpredictable components outside of the
418 deterministic range such as nonlinear wave amplification (e.g., Esler and Matthewman 2011;
419 Sjoberg and Birner 2014; Albers and Birner 2014) or tropospheric noise.

420 To see if the forecasts for the 2019 springtime SPV weakening correctly represent the
421 proposed low-frequency dynamical processes, we present the BoM forecasts initialized on 25
422 July 2019, which predicted the SPVI less than -1σ at the earliest (Fig. 9b). The 11-member
423 ensemble mean forecasts captured the increased upward propagating wave-1 activity and the
424 overall pattern of the lower tropospheric circulation anomalies in the SH high latitudes (Figs.
425 10a,b), demonstrating that a sequence of upward propagating wave events from the lower
426 troposphere acted to slow the upper stratospheric westerly jet. We further identified the three
427 ensemble members that predicted the least weakening of the springtime polar vortex (mean of
428 46 ms^{-1}) and the three ensemble members that predicted the most weakening (mean of 27 ms^{-1}).
429 We then formed the mean differences of $[U]$ at 60°S , the wave-1 activity flux, and August
430 mean $Z700$ between the two groups. The differences show that stronger predicted vortex
431 weakening is associated with stronger anomalies of upward wave-1 activity flux (Fig. 10c),
432 consistent with the notion that the abrupt warming and deceleration of the vortex were driven
433 by the anomalous upward wave flux. Interestingly, the $Z700$ difference pattern for the three
434 weakest and strongest vortex forecasts (Fig. 10d) more highly resembles the observed
435 anomaly pattern than the ensemble mean anomaly pattern does (Fig. 10c), providing
436 reassurance that more vigorous wave-1 activity injected from the particular lower troposphere
437 anomaly pattern depicted in Fig. 10d is associated with a considerably weaker springtime
438 polar vortex. However, this analysis of ensemble spread implies that, although the model
439 confirms the proposed dynamics for the vortex weakening event taking a season, the precise
440 prediction of the magnitude and timing of the SSW was not predictable at this relatively long
441 lead time because of the stochastic nature of the upward wave activity flux.

442 We also examine the predictability of the SH surface climate anomalies in October to
443 December 2019 that were promoted by the stratosphere-troposphere coupling in BoM
444 forecasts. As the BoM system skilfully predicted the springtime SPV weakening with the
445 initial conditions from late July, this system could make forecasts for the OND mean negative
446 SAM with initial conditions of late July onwards (Fig. 11a). However, the prediction
447 initialized on 9 August 2019 failed to produce the negative SAM because only a small
448 reduction in the vortex strength was predicted (Fig. 9b), which implies the dependence of the
449 predictability of late spring SAM on the predictability of the stratospheric polar vortex
450 weakening. The 66 BoM forecasts from the six different initialization dates from late July till
451 early September, represented by different color bars in Fig. 11a, further demonstrate a good
452 linear fit between the forecasts of the springtime SPV weakening and OND negative SAM
453 strengths (Fig. 11b).

454 We have shown in Figs. 6 and 7 that the SPV weakening and resultant negative SAM
455 was a key driver of the extreme hot and dry conditions over subtropical eastern Australia,
456 which contributed to one of Australia's worst wildfire seasons in the far eastern seaboard. To
457 confirm that relationship in the prediction, we have plotted the forecast OND mean SAM
458 versus the forecast OND mean Tmax and rainfall averaged over eastern Australia (east of
459 140°E) in Figs. 11c and 11d, respectively, using the 55 BoM forecasts initialized on 25
460 August and 1, 9, 17 and 25 September. The figures suggest that the more negative the SAM
461 was, the hotter and drier eastern Australia was in the forecasts, as evidenced by the
462 correlation of the forecast SAM with the forecast Tmax and rainfall being -0.41 and 0.44,
463 respectively (statistically significant at the 0.2% level). These correlations represent
464 independent evidence of the causal effect of the SAM on these impact-relevant quantities
465 because the SAM is not strongly correlated with CP El Nino or the IOD in those forecasts.
466 These relationships between the SAM and eastern Australian Tmax and rainfall forecasts of

467 OND are found in the ECMWF forecasts as well with even stronger correlations
468 (Supplementary Fig. S10).

469 Concluding remarks

470 Seventeen years after the first-ever observed major SSW over Antarctica in late September
471 2002, an equivalently spectacular weakening and warming of the stratospheric polar vortex
472 occurred in September 2019. The impact of the event on the SH surface climate lasted until
473 the end of December. Thanks to advances in the capability of dynamical forecast systems and
474 accumulated knowledge concerning the dynamics and impacts of SH stratospheric polar
475 vortex variability since the 2002 SSW, the 2019 SSW received timely attention from
476 researchers and forecasters, who were able to warn from late austral winter that there would
477 be a high chance of its occurrence with potentially significant impacts on the SH surface
478 climate throughout spring to the end of 2019 (Milinevsky et al. 2019; Hendon et al. 2019a,b).
479 A review of the BoM service for 2019 reports "the BoM provided at least 104 briefings to
480 governments, emergency services and likely affected sectors around the outlook for the fire
481 season (spring and summer). It was recorded that in the 2019 fire season around 19 million
482 hectares were burnt and 33 lives were lost. While horrific, these numbers may have been
483 considerably higher without strategic decisions made through the close information sharing
484 partnerships between the Bureau, Government and emergency services" (Climate Operations,
485 BoM; internal communication, 2020).

486 In this study, we have provided a comprehensive overview of the monthly to seasonal
487 timescale dynamics, climate impacts, and predictability of this remarkable event. Key
488 findings are:

- 489 • The 2019 springtime stratospheric polar vortex weakening was as strong as that of
490 2002 despite not qualifying as a major SSW. New records were set in spring 2019 for

491 the vortex weakening at the stratopause, the Antarctic warming in the mid-
492 stratosphere and the high ozone concentration.

- 493 • The 2019 event closely followed the canonical development of SH springtime
494 stratospheric polar vortex weakening events with a poleward shifted polar night jet in
495 early winter and record-high monthly mean upward propagating wave-1 activity in
496 August, which emanated from the lower troposphere with distinctive anticyclonic
497 circulation anomalies centered over the Bellingshausen-Amundsen Seas.
- 498 • The 2019 stratospheric vortex weakening and warming coupled down to the surface
499 from mid-October, and the resultant record negative SAM induced significant local
500 climate extremes over eastern Australia, southern New Zealand, eastern South
501 America and western Patagonia through December 2019.
- 502 • Among the well-known large-scale drivers of Australian climate for its warm seasons,
503 the SH springtime polar vortex weakening appears to have been the most influential
504 contributor to the hot and dry and therefore fire-prone climate conditions over the
505 subtropical eastern seaboard of Australia, which suffered from severe and prolonged
506 wildfires during the late spring and early summer period.
- 507 • The occurrence of the 2019 springtime stratospheric vortex weakening was
508 foreseeable from July, and its extreme amplitude was skilfully predicted from late
509 August by the state-of-the-art forecast systems analyzed in this study.
- 510 • The skilful prediction of the 2019 springtime stratospheric vortex weakening resulted
511 in the skilful prediction of the late spring negative SAM, whose strength was tied to
512 the strength of hot and dry forecasts over eastern Australia for late spring.

513 We have covered some key aspects of the 2019 stratospheric polar vortex weakening,
514 but many interesting details of this event remain to be explored. For example, we reported
515 substantial amplitude of the wave-2 heat flux in July, but its source, interaction with wave-1,

516 and contribution to the vortex weakening are yet to be understood. Also, Hurwitz et al. (2011,
517 2014) and Lim et al. (2018) showed a possible relationship of the Antarctic stratospheric
518 warming with central Pacific El Nino, which was present in 2019. Furthermore, the strong
519 positive IOD and associated Rossby wave train was a dominant feature in the SH troposphere
520 in late winter to early spring and might have interacted and/or interfered with the 2019
521 stratospheric vortex weakening and its downward coupling (e.g., Lim et al. 2020). Thus,
522 atmospheric model experiments forced with the observed versus climatological boundary
523 conditions may shed some light on the role of the extraordinary SST conditions of 2019 for
524 the different stages of the 2019 stratospheric vortex evolution.

525 Finally, the near-record polar cap total column ozone concentration observed in
526 spring 2019 appears to be largely driven by the stratospheric polar vortex weakening and
527 record warming (e.g., Salby et al. 2002; Randel et al. 2002; Wargan et al. 2020), but ozone
528 variations associated with the stratospheric polar vortex variations can feedback onto the
529 circulation and temperature changes and amplify the impact of the vortex anomalies on the
530 SAM in the troposphere (Hendon et al. 2020). Thus, how much of the negative SAM and
531 associated SH surface climate extremes of October-December 2019 was driven by the ozone
532 increase will be an interesting question to address, which will potentially benefit the future
533 development effort of dynamical seasonal forecast systems, in which ozone is currently
534 prescribed with monthly climatology (e.g., Seviour et al. 2014; Hendon et al. 2020) or
535 radiatively not interactive (e.g., Johnson et al. 2018).

824

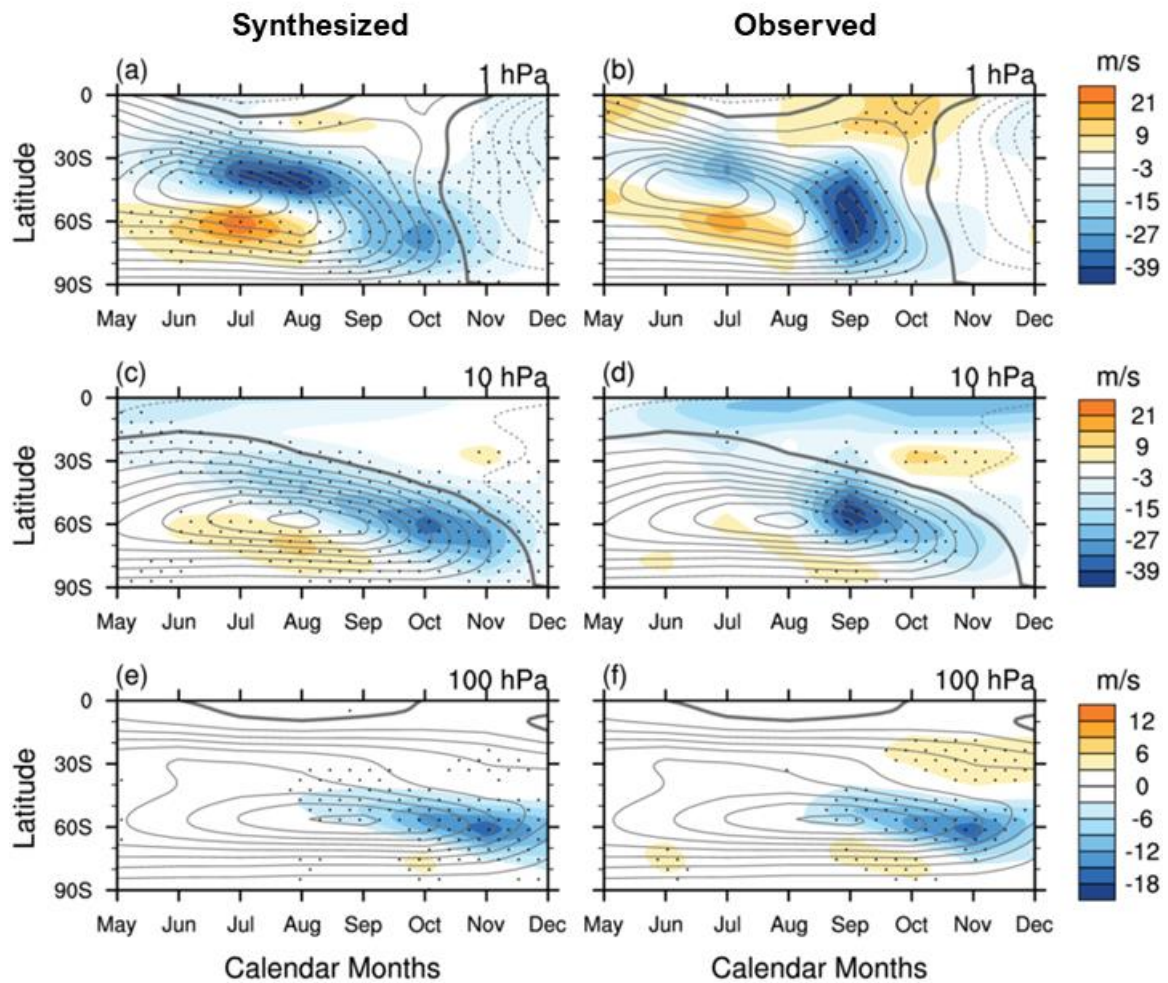

825

826 **FIG. 1.** Daily anomalies of (a) zonal-mean zonal wind ($[U]'$) at 60°S from 1000 to 1 hPa; (b)
 827 SAM as monitored by the Antarctic Oscillation (AAO) index by NOAA Climate Prediction
 828 Center (CPC); and (c) Antarctic polar cap temperatures averaged over 60-90°S. Time runs
 829 from June 1 to December 31 in 2019. The daily CPC AAO index in (b) is obtained by
 830 projecting daily 700-hPa geopotential height ($Z700$) anomalies onto the leading mode of the
 831 empirical orthogonal function (EOF) of monthly mean $Z700$ variability over the domain 20-
 832 90°S (Thompson and Wallace 2000). In (a) and (c) color shading indicates anomalies, and the
 833 overlaid contours indicate the climatologies computed over 1979-2018. Color shading
 834 intervals are (a) 10 ms^{-1} and (c) 6 K, and contour intervals are (a) 10 ms^{-1} and (c) 10 K,
 835 respectively. Stippling in (a) and (c) denote the 2019 anomalies fall in the $\pm 5\%$ tails of the
 836 climatological distribution as judged by the anomalies being greater than 1.68 standard
 837 deviations (σ) or less than -1.68σ , where σ is computed over 1979-2018.

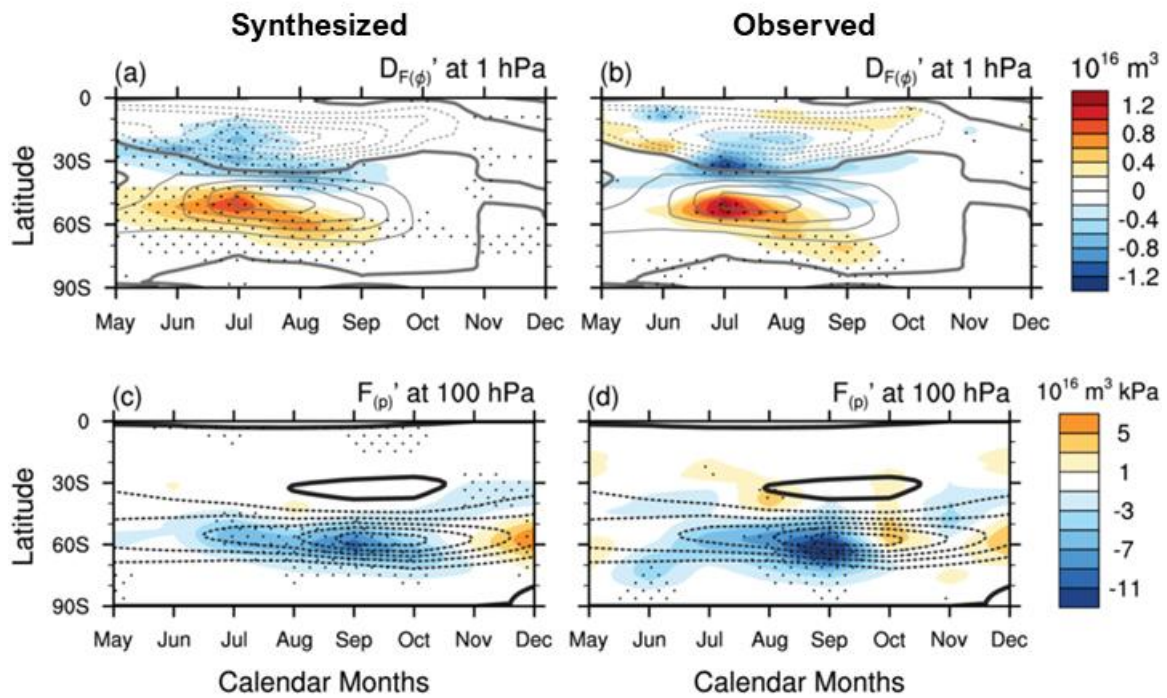

838

839 **FIG. 2.** Time series of anomalies of (a) September-November mean (SON) [U]' at 60°S at 1
 840 hPa; (b) same as (a) but at 10 hPa (i.e., the stratospheric polar vortex index, SPVI); (c) SON
 841 Antarctic temperature south of 60°S at 30 hPa; (d) SON Antarctic polar cap ozone (the data
 842 of total column ozone averaged over the polar cap south of 63°S were obtained from the
 843 NASA Ozone Watch page (<https://ozonewatch.gsfc.nasa.gov/>)); and (e) standardized
 844 October-December mean (OND) SAM (NOAA CPC monthly AAO) index. The dashed
 845 horizontal lines in each panel indicates a unit standard deviation.

846

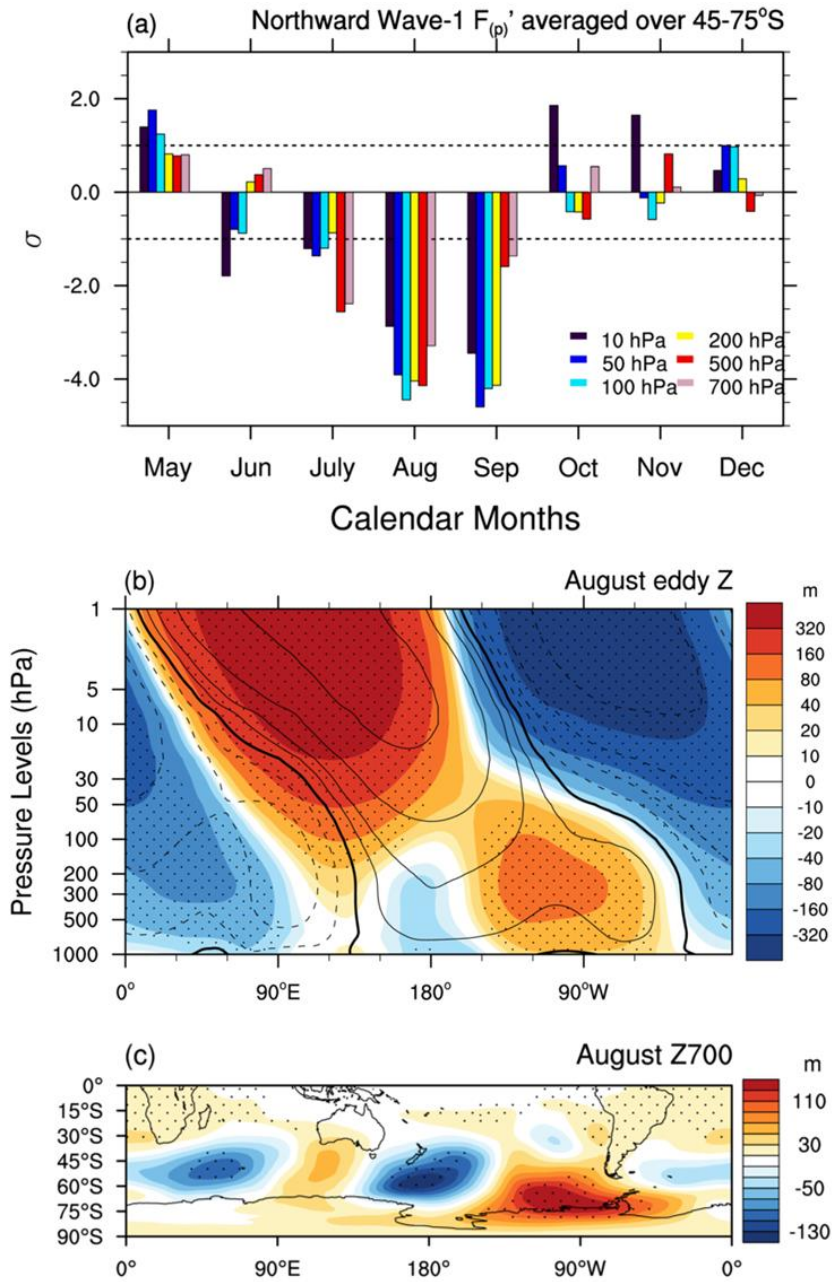

847 **FIG 3.** Latitude-time sections of monthly mean anomalies of zonal-mean zonal wind ($[U]'$)
 848 at (top) 1 hPa, (middle) 10 hPa and (bottom) 100 hPa. (Left panels) (a), (c) and (e) Syntheses
 849 of 2019 by regressing $[U]'$ at 1, 10 and 100 hPa onto the SPVI shown in FIG 2b for 1979-
 850 2018 and scaling the regression coefficients by the 2019 index magnitude (see Supplemental
 851 Material for further details). (Right panels) (b), (d) and (f) 2019 observed $[U]'$ at 1, 10 and
 852 100 hPa, respectively. Color shading indicates anomalies, and contours indicate the
 853 climatological winds. Color shading intervals are 6 ms^{-1} in (a-d) and 3 ms^{-1} in (e,f), and
 854 contour intervals are 10 ms^{-1} in (a-d) and 5 ms^{-1} in (e,f). Zero contours are thickened and
 855 negative contours are dashed. Stippling in the left panels denotes statistical significance of the
 856 regression coefficients at the 10% level, assessed by a two-tailed Student t-test with 40
 857 samples, and stippling in the right panels denotes extreme anomalies in the $\pm 5\%$ tails of the
 858 climatological distribution as described in FIG 1.

859

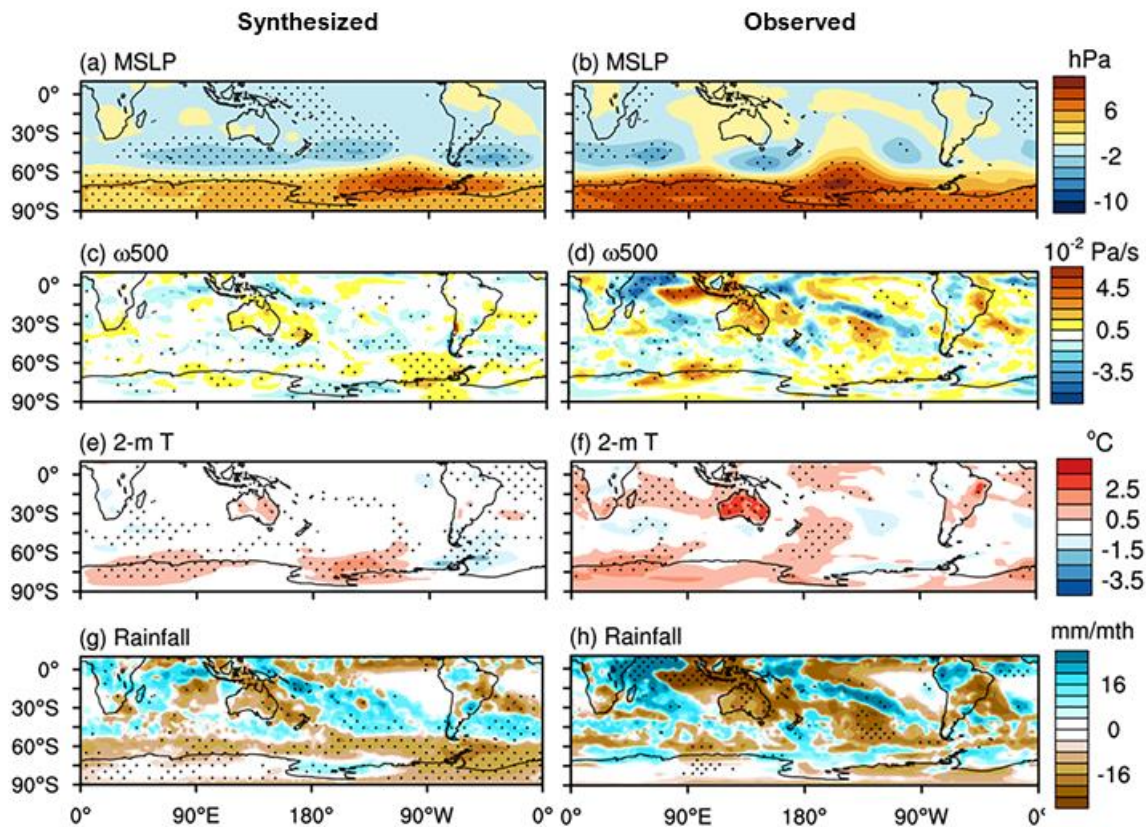

860 **FIG 4.** As in FIG 3 except for (top) the monthly mean anomalies of Eliassen-Palm (E-P) flux
 861 divergence ($D_{F(\phi)}'$) by the horizontal component ($F_{(\phi)}$) (i.e., momentum flux convergence) at
 862 1 hPa and (bottom) the vertical component of the E-P flux ($F_{(p)}'$); i.e., poleward eddy heat
 863 flux) at 100 hPa. In (c) and (d) negative values indicate the southward (i.e., poleward) heat
 864 flux in the SH representing upward wave propagation. The E-P flux and its divergence were
 865 computed on the spherical coordinate following Peixoto and Oort (1992). Color shading and
 866 contours show anomalies and climatologies, respectively, of $D_{F(\phi)}$ and $F_{(p)}$. The color shading
 867 interval is $0.2 \cdot 10^{16} \text{ m}^3$ for $D_{F(\phi)}$ and $2.0 \cdot 10^{16} \text{ m}^3 \cdot \text{kPa}$ for $F_{(p)}$, and the contour interval is
 868 $0.2 \cdot 10^{16} \text{ m}^3$ for $D_{F(\phi)}$ and $2.0 \cdot 10^{16} \text{ m}^3 \cdot \text{kPa}$ for $F_{(p)}$. Stippling indicates the statistical
 869 significance as described in FIG3.

870

871

872 **FIG 5.** (a) Standardized anomalies of poleward wave-1 heat flux ($F_{(p)}$) averaged over 45-
 873 75°S (with cosine weighting) at different vertical levels. (b) August eddy geopotential height
 874 (Z) averaged over 45-75°S with cosine latitude weighting. The contours and color shadings
 875 indicate climatological and 2019 eddy patterns, respectively. (c) Z700 anomalies for August
 876 2019. In (b) the color shading interval starts from -10 and 10 m and increases by two-folds,
 877 and the contour interval does the same but starting from -20 and 20 m. In (c) the color
 878 shading interval is 20 m. Stippling in (b) and (c) indicates extremity of anomalies found at
 879 the $\pm 5\%$ tails of the climatological distribution as described in FIG 3.

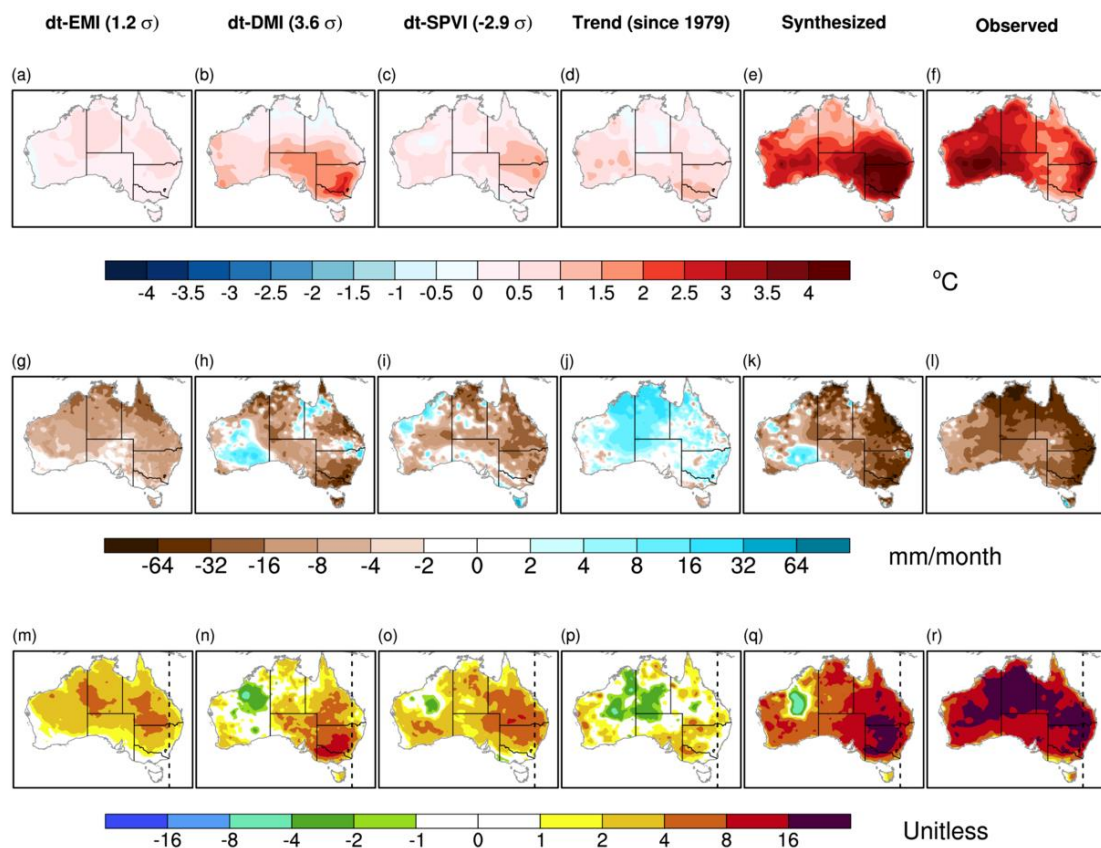

880

881 **FIG 6.** (Left panels) Syntheses of 2019 OND mean (a) mean sea level pressure (MSLP), (c)
 882 vertical velocity (ω) at 500 hPa, (e) 2-m air temperature and (g) rainfall anomalies derived
 883 from the regression onto the SPVI as described in FIG 3. The color shading interval is 2 hPa
 884 in (a), 0.01 Pa s^{-1} in (c), and $1 \text{ }^\circ\text{C}$ in (e). The color shading interval in (g) increases by two-
 885 folds for each level from 2 mm month^{-1} . (Right panels) Same as the left panels but the
 886 observed anomalies of 2019. Stippling indicates the statistical significance as described in
 887 FIG 3 except in (h) where stippling shows where the rainfall anomalies are found in the top
 888 and bottom decile categories.

889

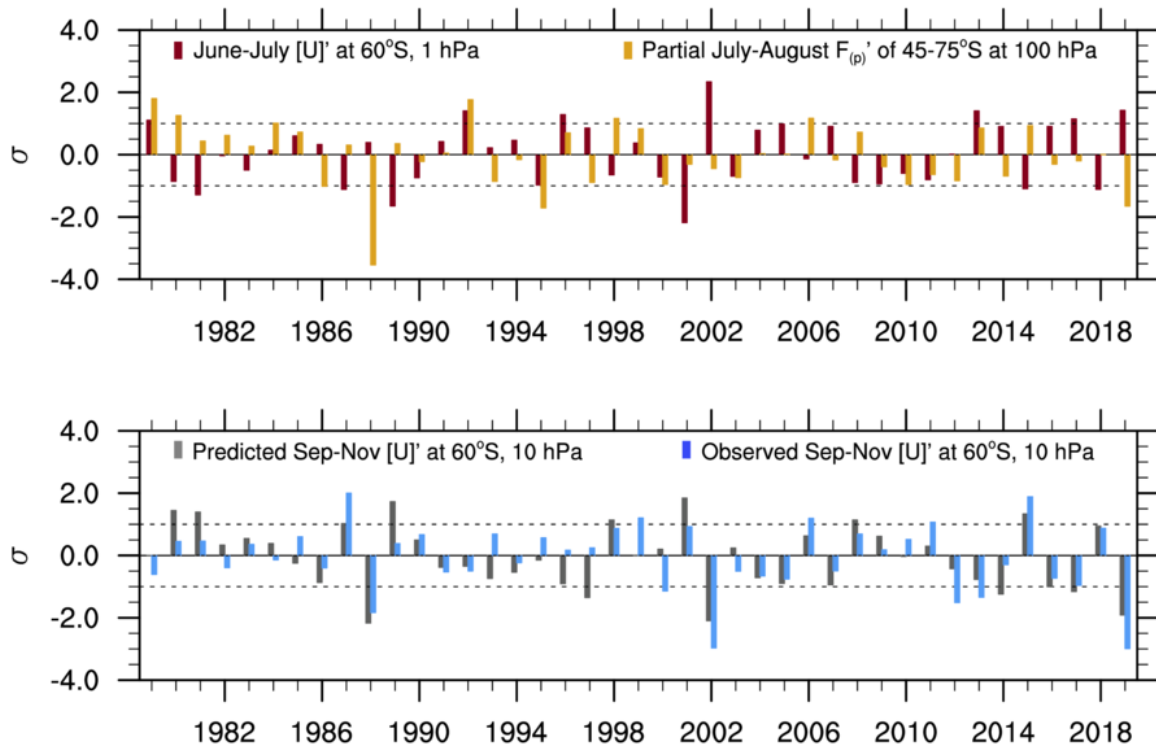

890

891

892 **FIG 7.** Patterns of OND mean Australian (top row; a-d) daily maximum temperatures;
 893 (middle row; g-j) rainfall; and (bottom row; m-p) daily forest fire danger index (FFDI)
 894 anomalies explained by (a,g,m) the de-trended El Nino Modoki Index (dt-EMI); (b,h,n) the
 895 de-trended Indian Ocean Dipole mode index (dt-DMI); (c,i,o) the de-trended spring polar
 896 vortex index (dt-SPVI; Fig. 2a); and (d,j,p) a linear trend of OND, using multiple linear
 897 regression built for 1979-2018. The regression coefficients are scaled by the 2019 amplitudes
 898 of the predictors as indicated by the numbers in the parentheses in the column titles. The
 899 synthesized anomalies of 2019 by the multiple linear regression model are displayed in (e),
 900 (k) and (q), and the observed anomalies of 2019 are displayed in (f),(l) and (r). The contour
 901 interval in the top panels is 0.5°C , while the intervals in the middle and bottom panels for
 902 respective rainfall and FFDI increase by two-fold for each level. The dashed vertical line in
 903 (m-r) marks 150°E as the area east of it experienced intense and prolonged bushfires in the
 904 OND season in 2019.

905

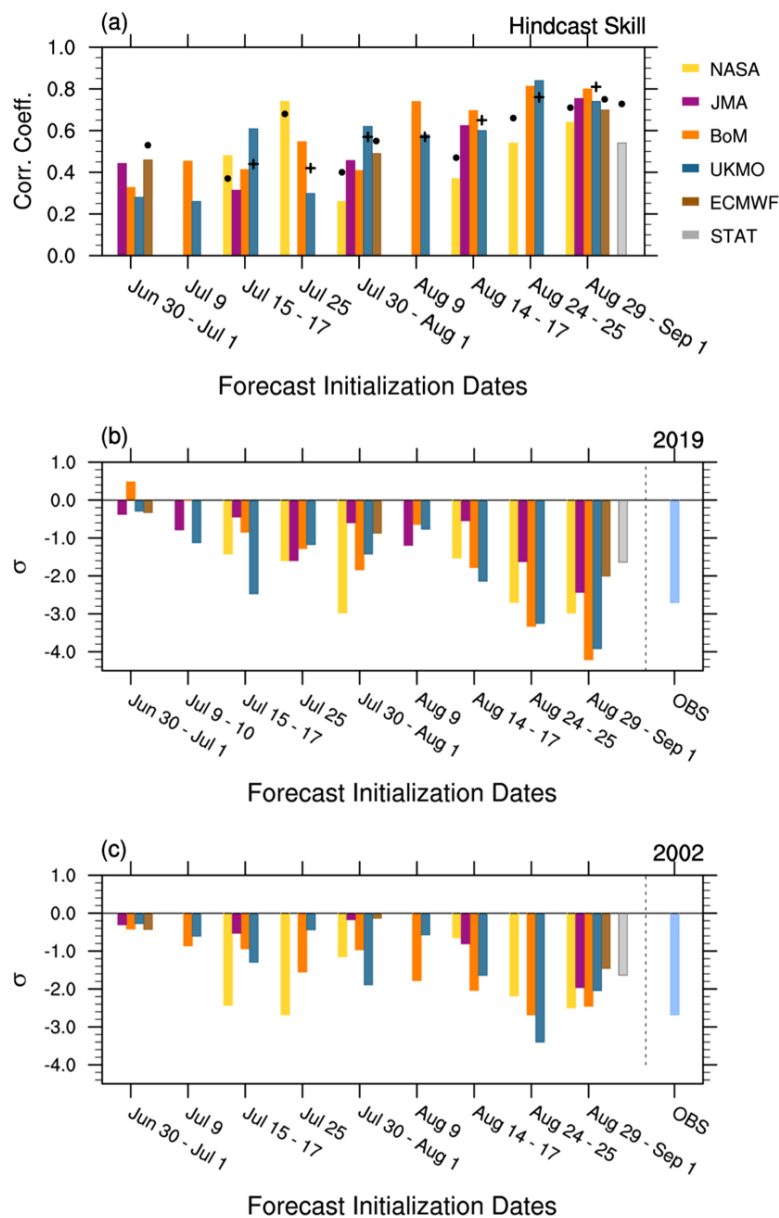

906

907

908 **FIG 8.** (Upper panel) Time series of June-July mean PNJ ($[U]'$ at 60°S) at 1 hPa (red bars),
 909 partial July-August mean northward heat flux ($F_{(p)}'$) independent of the June-July PNJ at 1
 910 hPa (orange bars); and (lower panel) statistically predicted SPVI (gray bars). The observed
 911 SPVI shown in FIG 2b is displayed in the lower panel again with light blue bars for
 912 comparison. The time series are normalized by their respective standard deviation (σ)
 913 obtained in 1979-2018. The horizontal dashed lines indicate $|1 \sigma|$.

914

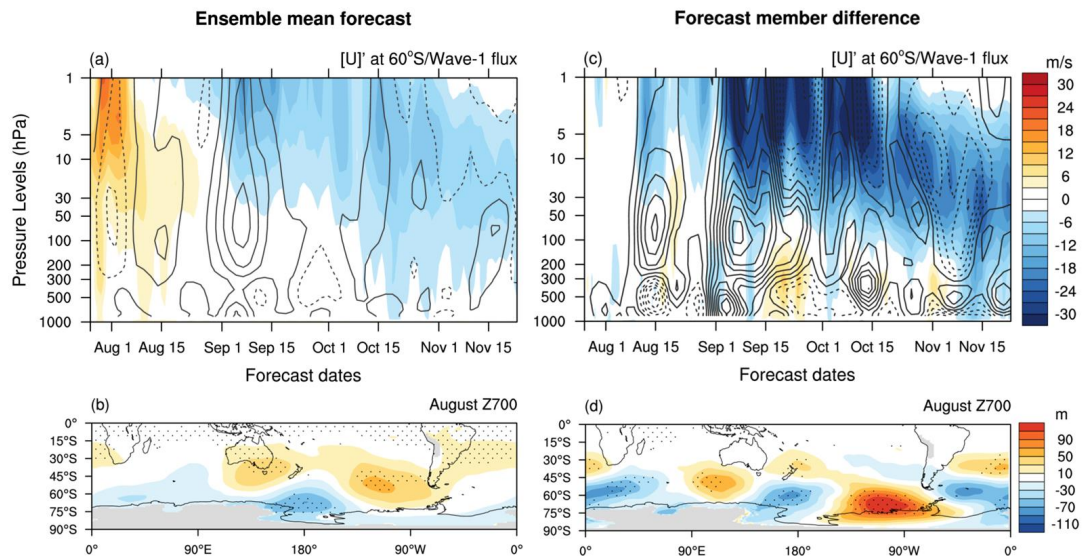

915

916 **FIG 9.** (a) Hindcast skill to predict the SPVI (as defined with FIG. 2b; SON [U]' at 60°S at
 917 10 hPa) from the five different operational center S2S forecast systems – NASA GEOS-S2S-
 918 2 (yellow), JMA/MRI-CPS2 (purple), BoM) ACCESS-S1 (orange), UKMO GloSea-5 (blue),
 919 and ECMWF-SEAS5 (brown). Skill of the statistical prediction discussed with Figure 8 is
 920 displayed with gray bars. All colored bars except for the blue bars (UKMO) represent the
 921 hindcast skill obtained over 1990-2012, for which the statistical model was re-built. The
 922 hindcast skill of the UKMO system was computed over 1993-2016. Black dots indicate the
 923 skill obtained over longer hindcast periods (see Table 1). The crosses overlayed with the blue
 924 bars indicate the skill with an increased ensemble size by using up to 17-day lags (compared

925 to 7-member burst ensemble used for the skill shown with the blue bars). (b,c) Dynamical
926 and statistical forecasts of standardized SPVI for 2019 and 2002, respectively. The observed
927 anomalies are displayed with light blue bars. All the forecast anomalies were computed with
928 each system's climatological mean and standard deviation from its hindcast periods. The
929 abscissa labels show the forecast initialization dates. Displayed dynamical forecasts are the
930 ensemble mean forecasts (except for NASA forecasts), and details of the forecast systems and
931 ensemble sizes are provided in Table 1.

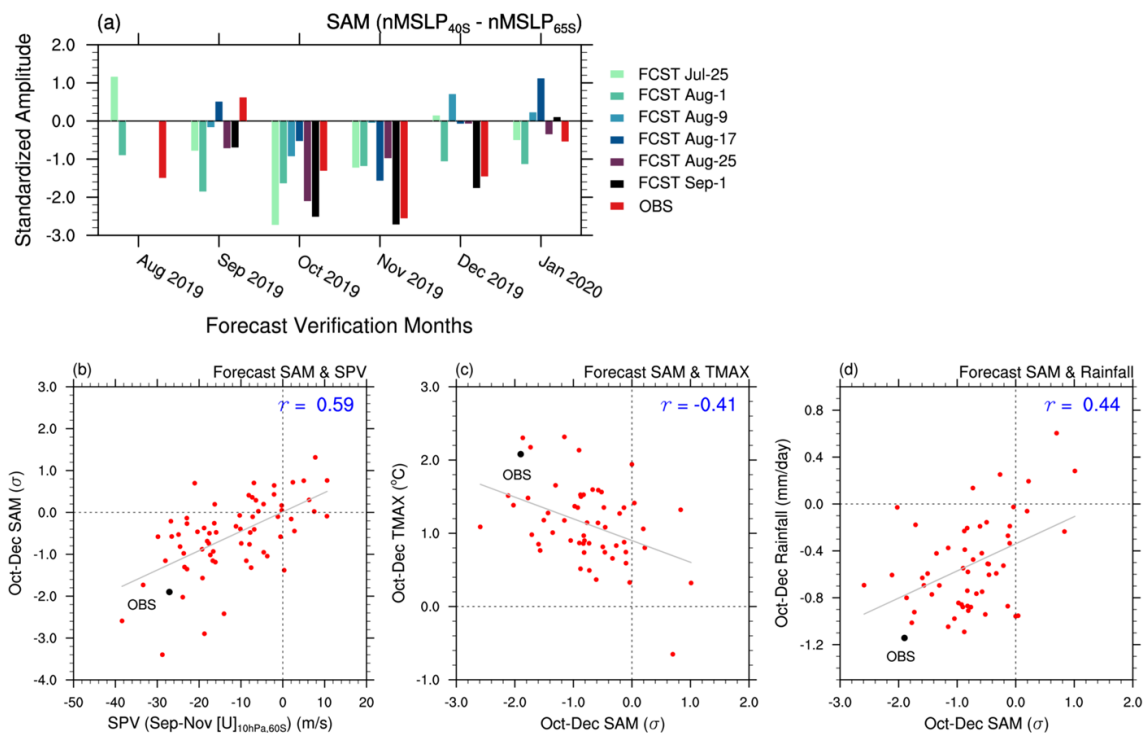

932

934

935 **FIG 10.** (Left panels) 11-member ensemble mean forecasts of (a) daily [U]' at 60°S (color
 936 shading) overlaid with standardized upward wave-1 activity flux ($F_{(p)}$; contours) and (b)
 937 August mean Z700 anomalies (color shading) from the BoM system. Forecasts were
 938 initialized on 25 July 2019. In (a) the solid (dashed) thick contour indicates the poleward
 939 (equatorward) heat flux and so upward (downward) wave propagation. Normalization of the
 940 wave activity flux by its standard deviation was done at each vertical level. Stippling in (b)
 941 indicates anomalies at the $\pm 5\%$ tails of the climatological distribution of BoM hindcasts.
 942 (Right panels) (c), (d) Same as in (a) and (b), respectively, except the mean differences
 943 between the three forecast members of the weakest spring polar vortex and those of the
 944 strongest spring polar vortex. The color shading interval is 3 ms^{-1} , and the contour interval is
 945 1σ starting from -11.5σ in (a) and (c). The color shading interval is 20 m in (b) and (d).
 946 Stippling in (d) indicates statistical significance on the difference of the two means at the
 947 10% level, assessed by a two-tailed Student t-test with the sample size of three in each group.

948

949

950 **FIG 11.** (a) BoM 11-member ensemble mean forecasts of monthly SAM initialized on 25
 951 July, 1, 9, 17, 25 August and 1 September of 2019. The forecast SAM values were computed
 952 by the normalized MSLP difference between 40°S and 65°S following Gong and Wang
 953 (1999)'s definition. The red color bars indicate the observed SAM values obtained from the
 954 British Antarctic Survey (<http://www.nerc-bas.ac.uk/icd/gjma/sam.html>), which was
 955 computed in the same way as Gong and Wang (1999)'s method but with station data
 956 (Marshall 2003). (b) 66 ensemble member forecasts (red dots) initialized on the dates shown
 957 in (a) for the SPVI and OND mean SAM. The observed values are displayed with the black
 958 dot. (c),(d) Relationship of the SAM with eastern Australian Tmax and rainfall (east of
 959 140°E, 10-45°S), respectively, in 55 forecasts (11 members initialised on 25 August, 1, 9, 17,
 960 25 September of 2019) for the OND season.

961

Operational Centers	Prediction Systems	Atmospheric resolution	Available full length of hindcast period	Hindcast Ensemble size per initialization date	2002/2019 forecast ensemble size per initialization date
