3 Cut-off Lows (COLs) in the Southern Hemisphere and the mechanisms involved in their  
4 development are investigated in detail using the eddy kinetic energy (EKE) budget  
5 applied to data from the ERA-Interim reanalysis. This approach considers the most  
6 important processes that are typical for the evolution of midlatitude disturbances such as  
7 the baroclinic (BRC) and barotropic (BRT) conversions, and the ageostrophic flux  
8 convergence (AFC), known as downstream development. Composites of the volume-  
9 integrated EKE and its components are evaluated based on the 200 most intense SH  
10 COLs (> 98th percentile) observed in a 36-yr period. Results show that the AFC  
11 together with the BRC conversion are the most important contributor to the EKE growth  
12 for the COLs, characterizing the downstream baroclinic development. The AFC plays  
13 an important role in genesis and intensification phases of the COLs, while the BRC  
14 conversion is important for the system maintenance. The dissipation of the COLs occurs  
15 due to dispersive fluxes (ageostrophic flux divergence) together with other processes  
16 not directly computed in the EKE equation, such as friction and latent heat release  
17 which are problematic in reanalysis datasets. The BRT conversion contributes  
18 negatively to the COL development by transferring EKE to the zonal flow kinetic  
19 energy, though this is not enough to dampen the intensification. Regional differences  
20 were found in the energetics, indicating that COLs originating upstream of the  
21 continents are clearly dominated by ageostrophic fluxes, while the systems over the  
22 Australian region are mostly driven by baroclinic processes.

Ageostrophic Flux Convergence.

## 25 **1 Introduction**

26 Over the past several decades, Cut-off Low (COL) systems have been attracting  
27 increasing attention from the forecasting and research communities, mainly because of  
28 the severe impacts that intense storms of this type can have on human activities. In the  
29 Southern Hemisphere (SH), COLs are one of the major synoptic-scale systems that  
30 contribute to the rainfall in subtropical regions (Llasat et al. 2007; Singleton and Reason  
31 2007; McInnes and Hubbert 2001). COLs have been found to be responsible for over  
32 half of the total precipitation in southeastern Australia (Pook et al. 2006), standing out  
33 as being the main controlling factor for the interannual variability of rainfall (Risbey et  
34 al. 2009). Moreover, COLs are distinct systems that can cause unusual precipitation in  
35 arid regions such as in the Namib and Kalahari Deserts in southern Africa (Muller et al.  
36 2008) and the Atacama Desert in the north Chilean Andes (Bozkurt et al. 2016).

37 During the past two or three decades, a variety of observational and modelling studies  
38 have been undertaken to guide our knowledge of COLs. Great efforts have been made  
39 to better understand COLs in regard to their typical behavior and the different physical  
40 and dynamical processes associated with them. A typical COL differs from the cold-  
41 core vortices found at higher latitudes as COLs generally originate equatorward of the  
42 main westerlies. The main climatological features of COLs such as where they are  
43 usually found, their trajectories, life span and seasonal variability are generally accepted  
44 in the published literature (Fuenzalida et al. 2005; Nieto et al. 2008; Reboita et al. 2010;  
45 Pinheiro et al. 2017), but the processes that control the intensification and maintenance  
46 of COLs have not previously been investigated extensively. A better understanding of  
47 the mechanisms that typically control the development of COLs may help to improve  
48 their representation in models and enable improved forecasting of COLs.

1  
2  
3 49 A large body of literature has documented the evolution of mid-latitude disturbances  
4  
5 50 since the classical studies of Charney (1947), Eady (1949) and Kuo (1949), contributing  
6  
7 51 to our understanding of baroclinic growth and barotropic decay. Later, other factors  
8  
9 52 have been considered that may influence the development of cyclonic disturbances in  
10  
11 53 subtropical and mid-latitudes, such as diabatic processes (Davis et al. 1993; Martínez-  
12  
13 54 Alvarado et al. 2014), surface fluxes (Kuo et al. 1991; Nogués-Paegle and Mo 1997;  
14  
15 55 Dal Piva et al. 2011), topography (Buzzi et al. 1987; Hayes et al. 1987; Gan and Rao  
16  
17 56 1994; Mikiyfunatsu et al. 2004), and the interaction between upper-tropospheric  
18  
19 57 potential vorticity (PV) with lower-tropospheric cyclonic features (Hoskins et al. 1985;  
20  
21 58 Mikiyfunatsu et al. 2004).

22  
23  
24  
25  
26 59 Although numerous previous studies have demonstrated that the contribution of  
27  
28 60 baroclinic processes are the most important for the growth of mid-latitude disturbances,  
29  
30 61 the concept based on the idea of atmospheric energy dispersion (Rossby 1945; Yeh  
31  
32 62 1949), the so-called downstream development (Simmons and Hoskins 1979), has  
33  
34 63 emerged as an essential mechanism for the development and maintenance of synoptic-  
35  
36 64 scale systems. According to this theory, the development of baroclinic eddies is the  
37  
38 65 result of the energy dispersed from decaying systems upstream, which propagate  
39  
40 66 eastward with a nearly Rossby wave group velocity (Pedlosky 1987; Chang and  
41  
42 67 Orlanski 1994). Orlanski and Sheldon (1995) observed that cyclone waves grow  
43  
44 68 initially due to the upstream energy source and later because of the baroclinic  
45  
46 69 conversion (EKE growing with ascent in the warm air and descent in the cold air)  
47  
48 70 referred to as downstream baroclinic development. Motivated by this context, other  
49  
50 71 authors have made use of the concept of downstream energy dispersion to provide a  
51  
52 72 dynamical interpretation of the baroclinic disturbances based on observations (Chang  
53  
54 73 1993; 2000; Danielson et al. 2004; 2006; Decker and Martin 2005; Dal Piva et al. 2010;  
55  
56  
57  
58  
59  
60

1  
2  
3 74 Rivière et al. 2015) or model simulations (Hoskins and Simmons 1979; Orlanski and  
4  
5 75 Chang 1993; Papritz and Schemm 2013; Schemm et al. 2013).

6  
7  
8 76 The perspectives obtained from the concept of downstream baroclinic development  
9  
10 77 have motivated the use of the local eddy kinetic energy (EKE) equation described by  
11  
12 78 Orlanski and Katzfey (1991) to explore the energy budget of cyclones, although very  
13  
14 79 few attempts have been made to investigate the energetics of COLs. Nevertheless, there  
15  
16 80 are a few studies, for example the study of Gan and Dal Piva (2013) who used the  
17  
18 81 National Centers for Environmental Prediction (NCEP) Department of Energy (DOE)  
19  
20 82 reanalysis to analyse the evolution of a COL in the South Pacific Ocean. They found  
21  
22 83 some differences in terms of the dominant mechanisms active in the COL studied  
23  
24 84 compared to typical extratropical cyclones, as the ageostrophic flux convergence (AFC)  
25  
26 85 was the main mechanism responsible for the EKE growth of the COL, whereas the  
27  
28 86 baroclinic (BRC) conversion played a secondary role, and was only important for the  
29  
30 87 genesis. The barotropic (BRT) term remained negative during the whole life cycle,  
31  
32 88 representing an important dissipative mechanism. These results were confirmed in a  
33  
34 89 composite study using fifty cases of COLs that occurred in the South Pacific Ocean  
35  
36 90 (Gan and Dal Piva 2016).

37  
38  
39  
40  
41  
42  
43 91 In a similar study, but using the Lorenz energetics (Lorenz 1955), Pinto and da Rocha  
44  
45 92 (2011) found that a particular disturbance associated with a mid-level COL located off  
46  
47 93 the southern Brazilian coast intensified due to the strong influx of available potential  
48  
49 94 and kinetic energy into the domain. These findings are consistent with the recent  
50  
51 95 demonstration that the zonal flow influences the COL development by advecting zonal  
52  
53 96 momentum from the large-scale jet streak in a nearly eastward direction (Ndarana et al.  
54  
55 97 2020). In addition, earlier studies have demonstrated that the downstream amplification  
56  
57 98 mechanism associated with upper-level cold lows off Northeast Brazil is a result of  
58  
59  
60

1  
2  
3 99 Rossby, and mixed Rossby-gravity wave dispersion (Silva Dias et al. 1983) with a  
4  
5 100 dominant period of 3-6 days with peak activity during the summer (Magaña and Yanai  
6  
7 101 1995; Yanai and Maruyama 1966). This type of disturbance can act as a precursor to  
8  
9 102 upper tropospheric vortices triggered by various processes such as lateral forcing (Mak  
10  
11 103 1969), thermal forcing (Lamb 1973), and wave-CISK (conditional instability of the  
12  
13 104 second kind) (Hayashi 1970).

14  
15  
16  
17 105 While the studies of Gan and Dal Piva (2013; 2016) have demonstrated that COL  
18  
19 106 development is indeed dominated by the energy originating from upstream regions  
20  
21 107 rather than directly from baroclinic processes, it is not clear whether the results therein  
22  
23 108 are robust enough to represent the energetics over a larger number of COLs, including  
24  
25 109 those located in other regions in the SH, because of the different nature of COLs, as  
26  
27 110 recently discussed by Pinheiro et al. (2020b). Given the poor understanding of the  
28  
29 111 energetics of COLs due to the limited sample size used in previous studies, the most  
30  
31 112 relevant scientific questions addressed in this paper are:

- 32  
33  
34  
35  
36 113 1. What are the main development mechanisms of the most intense SH COLs?  
37  
38  
39 114 2. Which mechanisms are the most important at specific stages of the COL life cycle,  
40  
41 115 and how do these mechanisms interact dynamically with each other?  
42  
43  
44 116 3. How do the mechanisms of COL development vary regionally?  
45  
46

47 117 The focus of the study is on the strongest systems because COLs generally cause  
48  
49 118 significant precipitation only if they are strong enough to be connected to cyclonic  
50  
51 119 features at lower levels (Pinheiro et al. 2020b), and which may lead to significant  
52  
53 120 moisture and heat transport from tropical latitudes into the system.

54  
55  
56 121 The paper continues in Section 2 with a description of the reanalysis dataset and the  
57  
58 122 methodologies used to identify and track COLs and to compute the EKE budget.  
59  
60

1  
2  
3 123 Section 3 presents the analysis of the composite energetics of austral COLs through  
4  
5 124 horizontal (vertically integrated quantities) and vertical cross-section fields. Section 4  
6  
7  
8 125 gives a summary of the main results and conclusions, and recommendation for future  
9  
10 126 work.

## 127 **2 Data and Methodology**

### 128 **2.1 Description of the ERA-Interim reanalysis**

129 The study uses six-hourly gridded data from the European Centre for Medium-Range  
130 (ECMWF) Interim (ERA-Interim) reanalysis to identify and track SH COLs and to  
131 compute energy budgets (from 1000 hPa to 100 hPa) during a 36-yr period (1979-  
132 2014). Following Pinheiro et al. (2020b, and references therein), we have chosen 300  
133 hPa relative vorticity and geopotential to analyze COLs as they are more frequent and  
134 intense at this level. The ERA-Interim reanalysis for the satellite era (1979 onward) uses  
135 a spectral model with TL255 horizontal resolution (~80 km) and 60 vertical hybrid  
136 levels with model top at 0.1 hPa. ERA-Interim is produced with four-dimensional  
137 variational data assimilation (4D-Var) system to assimilate the disparate quality  
138 controlled observations. A description of the ERA-Interim reanalysis is given by Dee et  
139 al. (2011). This dataset was chosen because this is in good agreement with other  
140 contemporary reanalyses regarding the identification of COLs (Pinheiro et al. 2020a).

### 141 **2.2 Track and identification**

142 In this study, the tracking algorithm described by Hodges (1995; 1999) is applied to the  
143 ERA-Interim reanalysis relative vorticity and geopotential data at 300hPa to track and  
144 identify SH COLs using the tracking criteria presented in Pinheiro et al. (2019) and the  
145 detection criteria based on the horizontal winds around the vortex center to separate  
146 COLs from other cyclonic systems. Before the tracking, the vorticity field is spectrally

1  
2  
3 147 truncated to T42 for vorticity as vorticity is a noisy field, while the geopotential field is  
4  
5 148 spectrally truncated at T63 as this is a smoother field. The tracking is performed on the  
6  
7 149 two fields independently using six-hourly data for the 300-hPa relative vorticity ( $\xi_{300}$ )  
8  
9 150 and 300-hPa filtered geopotential ( $Z'_{300}$ ). Filtered geopotential is obtained by removing  
10  
11 151 the zonal mean from the geopotential data for each time step and for each latitude, in  
12  
13 152 order to facilitate identification. The initial identification and tracking are as reported in  
14  
15 153 Pinheiro et al (2019). To ensure that the  $\xi_{300}$  and  $Z'_{300}$  minima are cut-off from the  
16  
17 154 westerlies, restrictive conditions are imposed to the horizontal wind components ( $u$ ,  $v$ )  
18  
19 155 in four offset points located  $5^\circ$  geodesic from the COL center which are  $0^\circ$  ( $u > 0$ ),  $90^\circ$   
20  
21 156 ( $v < 0$ ),  $180^\circ$  ( $u < 0$ ), and  $270^\circ$  ( $v > 0$ ) relative to North. Finally, we discard short tracks  
22  
23 157 (those with lifetimes less than 1 day) to avoid noise in the composites.  
24  
25  
26  
27  
28

### 29 158 **2.3 Composite energetics**

30  
31  
32 159 The energetics of extreme SH COLs are examined using composites of the 200 most  
33  
34 160 intense systems that are identified in both  $\xi_{300}$  and  $Z'_{300}$ , which exceed the 98th  
35  
36 161 percentile of the total number of matched COLs in the SH. Common systems are  
37  
38 162 identified using the same matching method as used in Pinheiro et al. (2020b). An  
39  
40 163 overview of the trajectories used in the composites is given in Fig. 1. The analysis is  
41  
42 164 based on the eddy kinetic energy (EKE) equation developed by Orlandi and Katzfey  
43  
44 165 (1991) and modified by Chang (2000). This is done by partitioning the processes  
45  
46 166 associated with the COL development into mean flow and perturbations (eddies), and  
47  
48 167 then analyzing individually the components of the EKE, which are represented in  
49  
50 168 Equation 1 as follows:  
51  
52  
53

$$\begin{aligned}
 54 & \\
 55 & \\
 56 169 & \frac{\partial \langle K' \rangle}{\partial t} = - \langle \nabla \cdot \vec{V} K' \rangle - \langle \nabla \cdot \vec{V}' \alpha' \phi' \rangle - \langle \omega' \alpha' \rangle - \left\langle \vec{V}' \cdot (\vec{V}'_3 \cdot \nabla_3) \vec{V} + \vec{V}' \cdot (\vec{V}'_3 \cdot \nabla_3) \vec{V}' \right\rangle - [\omega K']|_B + \\
 57 & \\
 58 170 & [\omega K']|_T - [\omega' \phi']|_B + [\omega' \phi']|_T + \langle \nabla \cdot \vec{V}'_v K' \rangle + \left[ \left( \frac{\partial p_s}{\partial t} + \vec{V}'_v \cdot \nabla p_s \right) K' \right] \Big|_B + \langle RES \rangle \quad (1) \\
 59 & \\
 60 &
 \end{aligned}$$

1  
2  
3 171 In Equation 1,  $K$  represents the kinetic energy,  $\alpha$  the specific volume,  $\vec{V}$  the horizontal  
4  
5 172 wind,  $\phi$  the geopotential,  $\omega$  the vertical velocity, and  $p_s$  the surface pressure. The  
6  
7  
8 173 overbar denotes the time-mean flow calculated for each month averaged over 28-31  
9  
10 174 days for the 6-hourly data. This is done separately for each individual month and year.  
11  
12 175 The primes represent the terms associated with the eddies (referring to the deviation  
13  
14 176 from the mean state), the superscript 3 the three-dimensional vector, the subscript  $a$  the  
15  
16 177 ageostrophic component, and the subscript  $v$  volume displacement velocity. The  
17  
18  
19 178 symbols  $\langle \rangle$  and  $[\ ]$  represent volume integrals taken from the bottom (chosen to be the  
20  
21 179 surface pressure, subscript  $B$ ) to the top (chosen to be the 100 hPa level, subscript  $T$ ).  
22  
23  
24 180 The term on the left-hand side of Equation 1 is the local tendency of EKE. The first  
25  
26 181 term on the right-hand side is the EKE flux convergence (KFC) which is associated  
27  
28 182 with the advective fluxes (Chang 2000). The 2nd term is the ageostrophic flux  
29  
30 183 convergence (AFC) due to the transfer of energy through the wave dispersion, known as  
31  
32 184 downstream development (Orlanski and Sheldon 1993). The 3rd term is the baroclinic  
33  
34 185 (BRC) conversion that is associated with the thermally-direct circulation with warm air  
35  
36 186 rising and cold air sinking. The 4th and 5th terms are the Reynolds stress or barotropic  
37  
38 187 (BRT) conversion which are associated with the horizontal wind shear. The BRT  
39  
40 188 process represents the rate of conversion from zonal to eddy kinetic energy associated  
41  
42 189 with transports of momentum. In mid-latitude transient disturbances the BRT  
43  
44 190 conversion is often related to system dissipation, though it may contribute to intensify  
45  
46 191 the disturbance in some tropical disturbance such as tropopause vortices near the North-  
47  
48 192 eastern Brazil region (Mishra et al. 2001). The 6th and 7th terms are the vertical  
49  
50 193 advection of energy through the lower boundary (i.e., surface pressure) and the upper  
51  
52 194 boundary (i.e., 100 hPa). The 8th and 9th terms represent the energy inflow through the  
53  
54 195 bottom and top boundaries due to the ageostrophic fluxes. The 10th term is the energy  
55  
56  
57  
58  
59  
60

1  
2  
3 196 flux due to movement of the volume integration, whereas the 11th and 12th terms  
4  
5 197 represent the energy variation due to the change in mass inside the volume integration.  
6  
7 198 The 10th-12th terms are not computed in this study due to the complexity in estimating  
8  
9 199 the energy fluxes associated with the movement of volume integrals. The 13th term is  
10  
11 200 the budget residual (*RES*) representing the mechanisms not explained in Equation 1  
12  
13 201 such as friction, errors in the calculation of diabatic terms in reanalysis, sub-grid flows  
14  
15 202 and errors introduced by numerical methods, such as interpolation and finite  
16  
17 203 differences. Another contributor to the residual may be associated with the analysis  
18  
19 204 increment in the reanalysis data which results from data assimilation procedures, which  
20  
21 205 may affect the energetics.

22  
23  
24  
25  
26 206 The tendency of EKE can be calculated using two different methods: the first one uses a  
27  
28 207 centered-time difference between the previous and subsequent time steps to compute the  
29  
30 208 left-hand side (LHS, observed tendency) of Equation 1, resulting in 12-h differences in  
31  
32 209 EKE. This is performed by considering the EKE in the volume that moves following the  
33  
34 210 system. The second way is to compute the tendency by summing all the terms on the  
35  
36 211 right-hand side (RHS, computed tendency) of Equation 1, except the 10th-12th terms  
37  
38 212 which will be part of the *RES*. The *RES* is estimated by the difference between the two  
39  
40 213 methods described above, i.e., the LHS minus the RHS.

41  
42  
43  
44  
45 214 The energetics are examined using a compositing methodology that has been previously  
46  
47 215 applied to tropical and extratropical cyclones (Bengtsson et al. 2007; Catto et al. 2010)  
48  
49 216 and more recently to subtropical COLs (Pineiro et al. 2020b). For the budget  
50  
51 217 calculations this is done by referencing the components of the EKE budget to a radial  
52  
53 218 grid with a prescribed radius centered on the COL center. Composites are also produced  
54  
55 219 for specific times relative to the time of maximum intensity of the COLs with respect to  
56  
57 220  $\xi_{300}$ . For the spatial composites, it is more convenient to use a rectangular grid, not

221 rotated according to the system propagation direction as in Catto et al (2010), which  
222 allows the examination of the COL horizontal tilt throughout the life cycle.

223 Energetic composites are vertically integrated from 1000 hPa (or surface) to 100 hPa,  
224 where the surface depends on the topography obtained from the reanalysis. This is  
225 particularly important over the mountain areas such as the Andes Cordillera, so that the  
226 energy is only computed above the surface. For more specific analyses, the energetics  
227 are also computed for each pressure level separately in exactly the same way as done by  
228 Chang (2000) applying his Equation 1, which is similar to our Equation 1 but without  
229 the 10th, 11th and 12th terms. This allows us to examine how each term of the EKE  
230 equation behaves in a vertical cross-section.

231 The area of the cylinder used for the calculations is considered to be fixed at a suitable  
232 prescribed radius, which will be chosen according to the practical purpose of the  
233 research and after considering how the residual in the EKE budget is affected by the  
234 chosen radial distance. Perhaps the main difference in approach between this study and  
235 previous ones is that we use a fully objective method to identify and track the system of  
236 interest, so that the energetics are computed directly over the COL center, avoiding  
237 subjective decisions on the system location, and minimizing contributions from  
238 advection of EKE through the boundaries. Moreover, the use of the algorithm facilitates  
239 using a larger number of systems for the compositing in comparison to manual  
240 procedures used to create composites, e.g., in Danielson et al. (2004) and Gan and Dal  
241 Piva (2016). For a regional analysis, the main genesis areas are identified and the tracks  
242 that have their genesis over a spherical region (radius=10°) centered on the maxima  
243 genesis are selected. This is done considering all identified COLs rather than using the  
244 strongest ones to ensure the analyses represent the typical EKE budget in each region.

### 245 **3 Results**

### 246 **3.1 Frequency distribution**

247 Given that the energetics may vary widely over all the SH COLs, we will first present  
248 an overview of the frequency distributions of the main energetic terms for all the SH  
249 COLs (total number is 11,542 tracks) identified in both  $\xi_{300}$  and  $Z'_{300}$ , i.e are identical  
250 systems in both fields, across the period 1979-2014. After a brief look at all the  
251 computed terms of Equation 1, we analyze the dominant terms through the distribution  
252 of the along-track mean values for the BRC, BRT and AFC terms (Fig. 2), which are  
253 integrated from the surface to 100 hPa and averaged over a  $15^\circ$  spherical cap region  
254 centered on each COL center. A visual inspection of the energetics revealed that the  
255 radial distance of  $15^\circ$  is appropriate to capture the main energy centers that control the  
256 COL development. The frequency distributions indicate that most storms have positive  
257 values of the BRC and AFC terms, while the BRT term is dominated by negative  
258 values, though variations in the distributions of these terms are observed. It is therefore  
259 apparent that SH COLs mainly intensify through the BRC and AFC mechanisms,  
260 although the contribution of these terms varies through time, as will be shown in the  
261 next section.

### 262 **3.2 The residual problem**

263 Before examining each term of the EKE budget, we provide a discussion of the residual  
264 which represents a factor of uncertainty in our work, existing mainly because of energy  
265 forcings that are not included in Equation 1 such as the friction and errors in estimating  
266 the diabatic processes by reanalysis (including the radiative, latent and sensible heat  
267 fluxes), but also because of energy fluxes related to the volume integration displacement  
268 and the variation of the mass in the volume, which are represented by the 10-12th terms.  
269 Inconsistencies can also be a result of the numerical error in the finite difference  
270 equations and the analysis increment in the reanalysis data. The residual is first assessed

1  
2  
3 271 to determine its magnitude for the strongest SH COLs using different radial distances  
4  
5 272 from the vortex center, such as 5°, 10°, 15°, 20° and 25° in geodesic distances (Fig. 3a).  
6  
7 273 This is done to provide an overview of the possible implications of the choice of  
8  
9 274 boundaries for the residual.

10  
11  
12 275 Fig. 3a shows that the estimation of the residual in the COLs depends on the size of the  
13  
14 276 measurement volume in which the values are calculated. In general, the larger the  
15  
16 277 horizontal area the smaller the amplitude of the residual throughout the COL lifecycle.  
17  
18 278 The largest amplitude of the residual is observed using 5° and 10°, but it decreases with  
19  
20 279 increasing area. The fact that the residual amplitude reduces with increasing volume  
21  
22 280 may be related to the transfer of energy across the boundaries (Muench 1965;  
23  
24 281 Michaelides 1987) where part of this transfer is represented by the energy flux (AFC  
25  
26 282 and KFC terms). Thus, the energy transport through the borders is probably more  
27  
28 283 important for relatively small regions (e.g., 5° or 10° geodesic radius) than in the outer  
29  
30 284 regions where the energy fluxes are relatively weak. However, if we set a large value  
31  
32 285 for the area, mechanisms that operate outside the system (i.e., other systems may be  
33  
34 286 included) may affect the EKE budget when using a large domain to perform the volume  
35  
36 287 integration.

37  
38 288 It can be seen from Fig. 3a that the residual is negative (rhs larger than lhs) throughout  
39  
40 289 the life cycle with radii equal or greater than 20 degrees and negative for most of the life  
41  
42 290 cycle with radii smaller than 20 degrees. The largest residuals are found in the decay  
43  
44 291 stage of the lifecycle. One reason for this “energetic imbalance” may be the unknown  
45  
46 292 contribution of the frictional dissipation, which represents an important energy sink for  
47  
48 293 the disturbance, though these effects are suggested to be not significant near the  
49  
50 294 tropopause (Cavallo and Hakim 2010). In a brief period of the COL development (from  
51  
52 295 ‘day -2’ to ‘zero’) the residual remains positive for the small radii (e.g., 5°, 10°, 15°),  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 296 which means there are other mechanisms that act as energy sources but that are not  
4  
5 297 directly computed or they are not correctly reproduced by the reanalysis, such as the  
6  
7 298 radiative cooling near the vortex, which was found to be important to intensify  
8  
9  
10 299 tropopause polar vortices (Cavallo and Hakim 2010). This will be discussed later with  
11  
12 300 regard to the spatial pattern of the residual. Despite the large variation in amplitude, the  
13  
14 301 average residual computed over the whole life cycle is not sensitive to the radius, as  
15  
16 302 shown in the legend of Fig. 3a.

17  
18  
19 303 The EKE tendency is calculated using two different methods (LHS and RHS of  
20  
21 304 Equation 1), as described in the methodology. These are shown in Fig. 3b, where a  
22  
23 305 significant correspondence for the EKE tendency between the RHS and LHS terms is  
24  
25 306 found during the growth phase of the COLs (defined as the time before the maximum  
26  
27 307 intensity of each COL), but marked differences occur in the decay phase (defined as the  
28  
29 308 time after the maximum intensity of each COL) that results in the large residual. The  
30  
31 309 difference between the LHS and RHS is negative when the COLs are decaying, and this  
32  
33 310 is probably related to effects associated with the friction and errors in diabatic heating  
34  
35 311 near the COL center. This energetic inconsistency is clearly evident in the curve of EKE  
36  
37 312 tendency obtained with the RHS when positive values appear during the decay phase,  
38  
39 313 indicating that there may exist dissipative mechanisms that are not included in the  
40  
41 314 formulation. The temporal evolution of the total EKE in the COLs (Fig. 3b) indicates  
42  
43 315 that the peak EKE coincides in time with the maximum intensity of the  $\xi_{300}$  COLs,  
44  
45 316 which is consistent with our expectation.

46  
47 317 The residual is now investigated by examining its time evolution in terms of the spatial  
48  
49 318 distribution for the period of two days (48 hours) before and after the peak intensity.  
50  
51 319 The distribution of the residual term is presented with the corresponding standard  
52  
53 320 deviation (Fig. 4) to examine the spread (dispersion) within the sample. This shows that

1  
2  
3 321 the negative residual maximizes immediately downstream of the COLs, particularly in  
4  
5 322 the mature and decay stages, and this suggests the presence of dissipation mechanisms  
6  
7 323 that are not considered in our approach or they are not well represented in the  
8  
9  
10 324 reanalysis. The large negative residual seems to be related to issues in the estimation of  
11  
12 325 latent heating release by the reanalysis, which we can also infer to be a fundamental  
13  
14 326 diabatic forcing in COLs. Particularly east of the COL, latent heat release may  
15  
16  
17 327 contribute to the generation of eddy available potential energy (EAPE) and later  
18  
19 328 converted to EKE by baroclinic conversion where warm ascent air is diagnosed (cf. Fig.  
20  
21 329 7b and Fig. 8b, which the ascent and precipitation is presumably collocated with warm  
22  
23  
24 330 air; see also a discussion of the precipitation in Pinheiro et al. (2020b)). This assumption  
25  
26 331 is intuitive considering that the precipitation in COLs (see Fig. 5 of Pinheiro et al.  
27  
28 332 2020b) spatially and temporally coincides with the spatial pattern of the negative  
29  
30  
31 333 residual energy. While diabatic heating does not directly contribute to the EKE budget  
32  
33 334 due to the fact that the EKE budget does not involve any diabatic heating terms, errors  
34  
35 335 in the reanalyses due to miss-representation of diabatic heating can easily introduce  
36  
37 336 uncertainties in the energetic framework, because diabatic heating can generate EAPE  
38  
39  
40 337 and then be converted to EKE by means of baroclinic conversion (Orlanski and Katzfey  
41  
42 338 1991). This is discussed further below.

43  
44  
45 339 Positive residual is found mainly upstream of the vortex center during the growth stage,  
46  
47 340 which seems to be placed in the region where the EAPE is converted to EKE in COLs  
48  
49  
50 341 (Ndarana et al. 2021). We hypothesize that the likely source of positive residual may be  
51  
52 342 related to issues in estimating the radiative cooling rates in the reanalysis, which  
53  
54 343 becomes less important as the cold core warms up. The results described above support  
55  
56 344 the idea that the latent heating acts to weaken the upper-level cold-core vortex  
57  
58  
59 345 (Garreaud and Fuenzalida 2007; Sakamoto and Takahashi 2005; Cavallo and Hakim  
60

1  
2  
3 346 2010), while radiative cooling is important for the system intensification (Cavallo and  
4  
5 347 Hakim 2010).

6  
7  
8 348 The fact that the EKE budget does not contain any diabatic heating terms implies that  
9  
10 349 there should be no direct influence of diabatic processes on the EKE budget. But this  
11  
12 350 would only be true on the assumption that the data used to compute the EKE budget is  
13  
14 351 all self-consistent such as would come from a free running model. However, this is not  
15  
16 352 the case with a reanalysis where a model first guess is adjusted towards the  
17  
18 353 observations, which vary in space and time, so that the analysis increment is strongly  
19  
20 354 dependent on the inhomogeneous observations, some of which are related to diabatic  
21  
22 355 processes (e.g., humidity). It has been shown in other studies (Guo and Chang, 2008;  
23  
24 356 Privé and Errico 2013;  
25  
26  
27  
28 357 <https://confluence.ecmwf.int/display/FUG/4.2+Analysis+Increments>) that the increment  
29  
30 358 can be large around regions of strong convection where the model depends on  
31  
32 359 parameterized diabatic processes and in addition the European Centre for Medium-  
33  
34 360 Range Weather Forecasts (ECMWF) model is a hydrostatic model which means that  
35  
36 361 miss-representation of these processes can result in large differences between the model  
37  
38 362 first guess and observations resulting in a large analysis increment. Differences can also  
39  
40 363 occur due to how certain observations (e.g., satellite data) are obtained and how they are  
41  
42 364 assimilated. This is likely to vary from time step to time step in the analysis as the  
43  
44 365 observations vary introducing noise into the reanalysis data which could be large if the  
45  
46 366 increments are large. This will affect all the data used in the budget calculation,  
47  
48 367 including the finite difference on the LHS, resulting in a contribution to the budget  
49  
50 368 residual. In addition, the analysis increments will likely vary through the COL lifecycle  
51  
52 369 as the influence of diabatic processes become important which is why we hypothesize  
53  
54 370 that the residual is large in the region of strong precipitation. These findings reinforce  
55  
56  
57  
58  
59  
60

1  
2  
3 371 the importance of diabatic processes for the development of COLs. The relative  
4  
5 372 contribution of diabatic cooling and heating could be quantified using a numerical  
6  
7 373 model, but this is beyond the scope of this study and is a matter for further  
8  
9 374 investigation.

### 10 375 **3.3 Energetics for strong Cut-off Lows**

11  
12  
13  
14  
15 376 The relative contributions of the main mechanisms for the development of the strongest  
16  
17 377 SH COLs are analyzed in this section in terms of the EKE budget. Given the set of  
18  
19 378 COLs is the same as used in Pinheiro et al. (2020b), their findings will be considered as  
20  
21 379 the basis to serve as information for the discussion presented in this paper. It can be  
22  
23 380 seen from Fig. 5 that the AFC is by far the most important contributor to the EKE  
24  
25 381 growth. The transport of energy due to ageostrophic fluxes occurs with the group  
26  
27 382 velocity of Rossby waves and represents the radiative part of the total energy flux that  
28  
29 383 exists due to the dispersive nature of the atmospheric waves (Pedlosky 1987; Chang  
30  
31 384 2000). The AFC acts to import EKE from upstream systems in the early stages of the  
32  
33 385 COL lifecycle, while strong dispersive EKE fluxes occur in the decay phase, serving as  
34  
35 386 the primary mechanism responsible for the increase/decrease of energy for the COL.  
36  
37 387 The AFC decreases in the system region as the COL approaches its maximum intensity.  
38  
39 388 At this time, the BRC conversion becomes the most important mechanism to maintain  
40  
41 389 the COL, converting eddy available potential energy (EAPE) to EKE (Oort and Peixoto  
42  
43 390 1983). The EAPE is also generated by diabatic heating, particularly during the mature  
44  
45 391 and decay stages of a COL, which is the time of the peak precipitation. The major  
46  
47 392 source of diabatic heating is generally found in the warm sector of midlatitude cyclones  
48  
49 393 (Carlson 1991). This is similar to what happens in the most intense COLs, where most  
50  
51 394 precipitation occurs on the east side, and this may contribute to enhance the horizontal  
52  
53 395 temperature gradient. However, when the convection occurs near the COL center, the  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 396 diabatic heating tends to warm the cold core leading to vortex dissipation (Kousky and  
4  
5 397 Gan 1981). The composite of the BRC term shows two peaks separated in time by  
6  
7 398 approximately four days. This behavior is likely to be caused by diabatic forcing and  
8  
9 399 will be discussed later in the paper.

10  
11  
12 400 The other part of the total energy flux is the advective flux (KFC) that has a large  
13  
14 401 magnitude, but only contributes to displace the EKE center (Chang 2000). This is  
15  
16 402 attributed to the movement of energy centers rather than the intensification of the  
17  
18 403 system, where its movement is given by the phase velocity (Chang and Orlanski 1993).  
19  
20 404 Positive values of KFC are seen during the growth stage and imply that the energy is  
21  
22 405 being advected into the COL, while negative values means that the energy is advected  
23  
24 406 out of the system during the decay stage. The BRT term remains negative during the  
25  
26 407 whole development phase, representing the main energy sink. Note that the BRT  
27  
28 408 conversion acts in opposition to the EKE growth, but this is not enough to prevent the  
29  
30 409 intensification of the COLs. In the decay, the BRT is nearly zero, thereby the AFC and  
31  
32 410 other dissipative mechanisms such as friction and diabatic heating are most important in  
33  
34 411 dissipating the COLs. The regional analysis undertaken later in this paper will  
35  
36 412 demonstrate that the damping mechanisms will be greater the greater the intensity of the  
37  
38 413 ageostrophic flow.

39  
40 414 The results partly confirm earlier findings (Gan and Dal Piva 2013; 2016) concerning  
41  
42 415 the dominance of the ageostrophic flux convergence (divergence) to the growth (decay)  
43  
44 416 of the COLs. However, our results reveal that the BRC conversion plays a greater  
45  
46 417 contribution to the development of COLs, particularly to their maintenance. The sum of  
47  
48 418 the energy gain over the entire life cycle of the COLs corresponds to  $58.3 \times 10^{15}$  Joule  
49  
50 419 for the AFC and  $51.8 \times 10^{15}$  Joule for the BRC term. Despite the smaller amplitude of  
51  
52 420 the BRC term compared to the AFC term (see Fig. 5), the former is the only term of the  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 421 EKE budget that remains positive during the whole life cycle, characterizing the main  
4  
5 422 EKE source for the COLs and the main mechanism for their maintenance.  
6  
7  
8 423 Recent studies have demonstrated the role of the jet stream on the development of  
9  
10 424 COLs in particular locations in the SH (Gan and Dal Piva 2013; 2016; Ndarana et al.  
11  
12 425 2020; 2021). We now compare the results from the previous papers against our findings  
13  
14 426 for the strongest systems and discuss how the jet stream affects the COL development  
15  
16 427 in terms of the EKE perspective. These features are shown in Fig. 6 as the temporal  
17  
18 428 evolution of spatial composites. The initial stage of the COL lifecycle ( $T = -48h$ )  
19  
20 429 begins with a pre-existing upper-level trough associated with a fairly broad EKE center  
21  
22 430 on the west side and a weaker EKE center on the east side of the trough. In the  
23  
24 431 following discussion we will also use the terms “rear” and “front” interchangeably in  
25  
26 432 referring to “west” and “east”, respectively. The wind speed field exhibits a split jet  
27  
28 433 structure caused by the convergence of vorticity advection (Ndarana et al. 2020). The  
29  
30 434 split jet formation deepens the trough-ridge system, promoting an influx of EKE from  
31  
32 435 the midlatitude jet into the rear side of the COL. The rear energy center grows  
33  
34 436 vigorously over the next day ( $T = -24h$ ) by receiving EKE from the upstream  
35  
36 437 midlatitude center by means of ageostrophic fluxes. As the rear EKE center matures, it  
37  
38 438 loses energy downstream to intensify the front EKE center. The rear EKE center starts  
39  
40 439 decaying just before the maximum intensity in the  $\xi_{300}$ , when there is no longer a  
41  
42 440 supply of energy from the upstream midlatitude system and also as a consequence of its  
43  
44 441 own export of energy downstream. At the mature stage ( $T = 0$ ), the east EKE center  
45  
46 442 reaches its maximum intensity and then starts to decay. The decaying stage ( $T \geq 24h$ )  
47  
48 443 is marked by an overturning flux as the EKE centers on the east and west sides merge  
49  
50 444 with each other to form a single center in the southern sector of the COL, resembling  
51  
52 445 the case in Gan and Dal Piva (2013) their Fig. 4. Similarly to Ndarana et al. (2020;  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 446 2021), the midlatitude jet propagates in the south-eastward direction during the early  
4  
5 447 stage and then exhibits a more zonal orientation in the late stage. The propagation of the  
6  
7 448 jet streak favors anticyclonic wave breaking, indicated by a deformation of isentropic  
8  
9 449 PV contours (blue contour), leading to the advection of the stratospheric PV anomaly  
10  
11 450 into the subtropical troposphere.

12  
13  
14  
15 451 The composite evolution of the strongest SH COLs is now examined separately for the  
16  
17 452 three main terms of the EKE budget (AFC, BRC and BRT) using vertically averaged  
18  
19 453 fields (Fig. 7) and vertical cross-sections in the W-E direction (Fig. 8). The horizontal  
20  
21 454 and vertical cross-sections are conveniently discussed together. The vertical cross-  
22  
23 455 sections were examined along a line west-east at latitude zero (i.e., where the vorticity  
24  
25 456 center is located in each COL) as well as considering averages over latitudinal bands of  
26  
27 457 different widths. We found that the gradient of the EKE is significantly enhanced near  
28  
29 458 the COL center, thus the vertical cross-sections provided here are taken through a line  
30  
31 459 west-east at latitude zero. Fig. 7 shows that the evolution of the strong COLs is  
32  
33 460 preceded by an upstream baroclinic wave, following the idealized model described by  
34  
35 461 Orlanski and Sheldon (1995). The source region along the midlatitude jet supplies  
36  
37 462 energy via baroclinic conversion (Fig.7 middle), which is transferred to the rear side of  
38  
39 463 the COL. The energy dispersion occurs via ageostrophic fluxes oriented in a  
40  
41 464 northeastward direction (Fig. 7 top) and evolves in a wave train propagation that  
42  
43 465 alternates with divergence and convergence regions (negative and positive AFC),  
44  
45 466 similar to Rossby wave pattern propagation (Müller et al. 2015). This process is a clear  
46  
47 467 signature during the growth stage ( $T = -48h$  and  $T = -24h$ ) and is observed over the  
48  
49 468 upstream ridge associated with the PV overturning region (Knippertz and Martin 2007;  
50  
51 469 Ndarana and Waugh 2010; Ndarana et al. 2021; Barnes et al. 2021). During the whole  
52  
53 470 life cycle, the fluxes act to transport energy from the rear to the front of the COL,  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 471 contributing to the decay of the rear EKE center and growth of the front EKE center, as  
4  
5 472 discussed above. Such transfer of energy reaches a maximum strength between  
6  
7 473  $T = -24h$  and  $T = 0$ . The vertical cross-sections show that the energy transfer occurs  
8  
9 474 preferably at high levels where the ageostrophic winds have a major contribution.  
10  
11 475 However, when the COLs are considered individually rather than as a composite, some  
12  
13 476 cases can exhibit the largest values of AFC at mid-levels simultaneously with  
14  
15 477 intensification of baroclinicity (not shown). This configuration has also been observed  
16  
17 478 in midlatitude disturbances, such as in the mature stage of the Storms *Friedhelm* and  
18  
19 479 *Klaus* in the North Atlantic Ocean (Rivière et al. 2015) where the ageostrophic fluxes  
20  
21 480 are found to be larger at  $\sim 500$  hPa.  
22  
23  
24  
25

26 481 The integrated and vertical distributions of the BRC term provide a comprehensive  
27  
28 482 picture of the baroclinic process and its contribution to the development of COLs. This  
29  
30 483 is given in Figs. 7 and 8 (middle). The BRC conversion from EAPE to EKE occurs  
31  
32 484 whenever the thermally direct circulation is active. As discussed before, the upstream  
33  
34 485 energy source associated with the midlatitude jet is the primary mechanism for  
35  
36 486 intensifying COLs. The energy transfer via ageostrophic fluxes maximizes between  $T$   
37  
38 487  $= -48h$  and  $T = -24h$  together with local baroclinic processes that take place just  
39  
40 488 behind the COL because of the sinking cold air (see also supplementary material Fig.  
41  
42 489 S1), characterized by the early BRC peak shown in Fig. 5. The western EKE source  
43  
44 490 starts to decrease during the period of peak intensity, but then another energy source  
45  
46 491 evolves further east, because of the ascending warm air at mid and upper tropospheric  
47  
48 492 and lower stratospheric levels (responsible for the late BRC peak). The upward motion  
49  
50 493 is likely reinforced due to latent heat release in the warm air, which generates EAPE and  
51  
52 494 consequently intensifies the baroclinic conversion. This is a particular feature of the  
53  
54 495 strongest COLs and hence longer lifetimes are observed compared to less intense  
55  
56  
57  
58  
59  
60

1  
2  
3 496 systems. The results of this paper are consistent with Gan and Dal Piva (2013) and  
4  
5 497 Ndarana et al. (2021), though our composites show a greater contribution from  
6  
7 498 baroclinic processes, particularly because of the enhanced ascent in the most intense  
8  
9 499 COLs, a feature that has not been previously reported. The energetics of the strong  
10  
11 500 COLs exhibit a similar pattern to those shown by Danielson et al. (2004) for  
12  
13 501 extratropical cyclones, corroborating the existence of a vertical coupling between upper-  
14  
15 502 level COLs and low-level cyclones, as discussed in Pinheiro et al. (2020b).

16  
17 503 Regions of positive (negative) BRC seem to be spatially correlated with regions of  
18  
19 504 negative (positive) AFC. The assumption of interdependence between the AFC and  
20  
21 505 BRC terms has been checked by examining the spatial correlation between these terms.  
22  
23 506 We find an average correlation coefficient of -0.6 between the AFC and BRC terms,  
24  
25 507 suggesting that the energy produced (dissipated) via the BRC conversion is dispersed  
26  
27 508 (accumulated) through the ageostrophic fluxes. The temporal correlation between the  
28  
29 509 AFC and BRC terms (computed over a spherical cap of 15 degrees) is negative at all  
30  
31 510 stages of the lifecycle, reaching its largest value (-0.86) near the time of maximum  
32  
33 511 intensity of the COLs. The combined action of the two mechanisms discussed above  
34  
35 512 constitutes to the downstream baroclinic development.

36  
37 513 The spatial composite of BRT conversion (Fig. 7 bottom) indicates that most of the  
38  
39 514 COL region is dominated by negative values, particularly upstream from the COL  
40  
41 515 center in the growth phase. This means that the horizontal shear upstream from the COL  
42  
43 516 contributes to the zonal flow that extracts kinetic energy from the COL. In contrast, a  
44  
45 517 minor contribution associated with barotropic conversion (positive values) occurs on the  
46  
47 518 eastern EKE center in the late stages, though this is much less important than both the  
48  
49 519 AFC and BRC processes. It is important to say that, despite the poor efficiency in  
50  
51 520 generating kinetic energy, the barotropic instability was found to be the dominant  
52  
53  
54  
55  
56  
57  
58  
59  
60

521 mechanism for the development of synoptic disturbances in tropical and subtropical  
522 regions (Colton 1973; Rao and Bonatti 1987; Mishra et al. 2001; 2007; Pinto and Rocha  
523 2011).

### 524 **3.4 Regional analysis**

525 In section 3.2, the evolution of the main terms of the EKE budget were investigated.  
526 Here, the energetics are analyzed in detail using sector averages as these may vary  
527 regionally. The focus is on the sectors situated in the vicinity of the continents, which  
528 have been chosen based on the main genesis areas, selected over a spherical region  
529 (radius=10°) centered on the maxima of genesis for eight regions (Fig. 9): A (32°S,  
530 10°E), B (29°S, 39°E), C (33°S, 105°E), D (34°S, 142°E), E (33°S, 161°E), F (34°S,  
531 166°E), G (34.5°S, 80°W) and H (35°S 57°W). The selection is made using all identified  
532 COLs (number of tracks for each region is indicated in the caption of Fig. 10), thus this  
533 guarantees that the analysis represents the typical EKE budget in each region. Fig. 10  
534 shows the composite temporal evolution of the main energy terms with their  
535 corresponding standard deviation obtained in each of the eight regions. As expected, the  
536 two terms of the EKE budget that most contribute to the intensification of the COLs in  
537 all regions are BRC and AFC, while decay is dominated by dispersive ageostrophic  
538 fluxes (negative contribution of the AFC term) with BRT conversion (negative  
539 contribution) playing an important role in dissipating only the COLs in regions A, G  
540 and H (for more detail see Table I). There are, however, substantial regional differences  
541 in the relative contribution of the BRC and AFC terms for the intensification phase. We  
542 see that COLs formed upstream of the main continents (regions A, C and G) are clearly  
543 dominated by ageostrophic fluxes, as indicated by the largest maxima in AFC, agreeing  
544 with the results of Gan and Dal Piva (2013; 2016) for region G. This is also the case for  
545 the COLs in region B, though the ageostrophic fluxes are much weaker than those

1  
2  
3 546 associated with the COLs situated over the windward side of continents. On the other  
4  
5 547 hand, the COLs located in southeast Australia and western Pacific (regions D, E and F)  
6  
7 548 are mostly driven by baroclinic processes. For the COLs originating in sector H, the  
8  
9 549 AFC and BRC terms contribute more or less equal to their growth. Although each  
10  
11 550 region is influenced differently by each mechanism, there is a large variation in the  
12  
13 551 contribution of the dominant mechanisms, particularly relating to the AFC that presents  
14  
15 552 the highest standard deviation among all terms of the EKE budget.  
16  
17  
18

19 553 Previous studies have suggested that the cut-off phenomena is a result of distinct RWB  
20  
21 554 scenarios (Thorncroft and McIntyre 1993; Ndarana and Waugh 2010; Portmann et al.  
22  
23 555 2020). The detailed analysis of the energy budget in different genesis regions suggests  
24  
25 556 that the COLs originating in regions A, B, C and G may be influenced by stationary  
26  
27 557 Rossby waves induced by surface topography that generally break anticyclonically,  
28  
29 558 advecting high PV anomalies equatorward. The anticyclonic barotropic shear facilitates  
30  
31 559 the transfer of EKE from the upstream midlatitude jet to the downstream EKE center  
32  
33 560 associated with the COL, as demonstrated in earlier studies as well as here. While the  
34  
35 561 downstream development appears to be the most important mechanism to COL growth  
36  
37 562 in the aforementioned regions, the COLs that occur in southeast Australia, New Zealand  
38  
39 563 and the western Pacific (regions D, E and F) are much less influenced by the  
40  
41 564 ageostrophic fluxes. It is not clear what the reason for the differences are, but we  
42  
43 565 hypothesize that the primary mechanisms for the evolution of a COL may be related to  
44  
45 566 the circulation structure and the type of the RWB. Peters and Waugh (2003) showed  
46  
47 567 that most of the RWB events in austral latitudes present an anticyclonic behavior with  
48  
49 568 deformed PV contours tilting westward, while cyclonically RWB events (i.e., when PV  
50  
51 569 contours tilt eastward and roll up cyclonically) are more common in the Australian  
52  
53 570 region. This is likely caused by the presence of a split jet structure in the Australian  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 571 region, which becomes more apparent during the austral winter (Peters and Waugh  
4  
5 572 2003; Ndarana and Waugh 2011), though there is a large interannual variability (Elsholz  
6  
7 573 et al. 2001). However, observational studies are too limited to cover the wide range of  
8  
9 574 scenarios, and such assumptions need further study.

#### 12 575 **4 Discussion and conclusions**

15 576 The results of this study provide insights into the main development mechanisms in  
16  
17 577 austral COLs by analyzing the relative contributions of the components of the EKE  
18  
19 578 budget for the most intense COLs across the whole hemisphere and also within eight  
20  
21 579 regions of interest. The AFC together with the BRC conversion are found to be the  
22  
23 580 primary mechanisms for the COL development. Results provide evidence of an  
24  
25 581 interdependent association between the downstream energy fluxes and BRC conversion  
26  
27 582 as these processes act by cancelling each other. Over the regions where the BRC term is  
28  
29 583 positive (negative), the AFC tends to be negative (positive) as the ageostrophic fluxes  
30  
31 584 act to export (import) the kinetic energy created (destroyed) by BRC conversion  
32  
33 585 downstream (from upstream). The AFC is crucial for the formation and intensification  
34  
35 586 of the COLs, while the BRC conversion is important throughout their lifecycle,  
36  
37 587 representing the main mechanism to maintain the system.

38  
39 588 The development of COLs agrees well with that described by Orlanski and Sheldon  
40  
41 589 (1993) in which cyclone waves grow initially due to the energy dispersed by upstream  
42  
43 590 systems and later because of the baroclinic conversion. The EKE life cycle of COLs is  
44  
45 591 not particularly unique, rather it is variation in the development of typical midlatitude  
46  
47 592 disturbances. There is, however, an important difference between the results described  
48  
49 593 above and the conceptual model of Orlanski and Sheldon (1993), as the decay stage of  
50  
51 594 the strong COLs is marked by an overturning and a partial interruption of the energy  
52  
53 595 wave train propagation likely as a consequence of the Rossby wave breaking. This can

1  
2  
3 596 be seen, for example, in the ageostrophic fluxes orientated south-westward in the decay  
4  
5 597 stage, thus redistributing the EKE within the system. This characteristic seems to be  
6  
7 598 what differentiates the energetics of the COLs from a regular trough.  
8  
9

10 599 The initial preconditioning mechanism takes place upstream of the upper-level trough  
11  
12 600 that will originate the COL, where a source region along the midlatitude jet supplies  
13  
14 601 kinetic energy via baroclinic conversion, which is exported to the rear side of the  
15  
16 602 incipient COL. The ageostrophic fluxes converge into the domain that give rise to net  
17  
18 603 ageostrophic flux convergence and EKE growth during the development phase and net  
19  
20 604 ageostrophic flux divergence and EKE decay during the decay phase. The processes  
21  
22 605 described above occur simultaneously in each sector of the COL, but the magnitude of  
23  
24 606 the AFC varies throughout the lifecycle, thus the EKE tendency will depend on the  
25  
26 607 dominant relation between convergence and divergence of ageostrophic fluxes.  
27  
28  
29  
30

31 608 While the ageostrophic fluxes contribute to the EKE growth only during the growth  
32  
33 609 stage, the BRC conversion is the only term that remains positive over the entire life  
34  
35 610 cycle, representing the main EKE source for the COLs. Results have shown that the  
36  
37 611 BRC conversion is important for both formation and maintenance of COLs, presenting  
38  
39 612 two distinct peaks during their life cycle. The first one occurs in the development phase  
40  
41 613 and is mainly associated with descent of cold air along the western edge of the COL  
42  
43 614 cold core. The second peak occurs in the decay phase and is due to the ascent of warm  
44  
45 615 air on the eastern side of the COLs, which occurs within the stratospheric warm core  
46  
47 616 and extends down to a warm region further east (shown in the supplementary material,  
48  
49 617 Fig. S1). The EKE production related to the BRC conversion maximizes in regions of  
50  
51 618 strong temperature gradients around the vortex and is a robust feature of the strongest  
52  
53 619 COLs, indicating that baroclinic processes are consistently more frequent in the main  
54  
55 620 baroclinic zones. These findings complement the recent study by Pinheiro et al.  
56  
57  
58  
59  
60

1  
2  
3 621 (2020b), and extend their observations on the structural features to a more dynamical  
4  
5 622 view of the energetics of the strong COLs.  
6  
7

8 623 While the composite features support evidence of downstream development in COLs,  
9  
10 624 the results do not seem to be robust enough to represent the wide variety of possible  
11  
12 625 development scenarios. The regional analysis reveals substantial differences in the  
13  
14 626 relative contributions of the main energetics terms in eight sectors in the SH. For  
15  
16 627 example, the groups of COLs originating upstream of the continents are characterized  
17  
18 628 by a large contribution of ageostrophic fluxes, while those systems located in the  
19  
20 629 Australian region have weak ageostrophic geopotential fluxes and are mainly driven by  
21  
22 630 baroclinic conversion. This shows that the upstream influence in the Australian COLs is  
23  
24 631 quite weak compared to other regions, and suggests that such differences may occur in  
25  
26 632 response to the type of Rossby wave breaking, as discussed before.  
27  
28  
29

30  
31 633 Another question that naturally arises is what makes the COLs so strong? Sensitivity  
32  
33 634 analysis based on the system intensity (not shown) reveals that the mechanisms leading  
34  
35 635 to increasing energy in the strongest systems (e.g., AFC and BRC conversion) are large  
36  
37 636 enough to compensate the large effect of the damping mechanisms such as the BRT  
38  
39 637 conversion and friction. In addition, diabatic mechanisms that occur during the  
40  
41 638 development of the COLs may contribute to their further intensification.  
42  
43  
44

45  
46 639 One of the issues in exploring the EKE budget with reanalysis data is the relatively  
47  
48 640 large residual observed by the composites, particularly from the mature to decay stages  
49  
50 641 of the COLs (see Figs 3 and 4). One factor that may contribute to the residual is the  
51  
52 642 unknown contribution from the friction, which is difficult to assess because this is “not  
53  
54 643 computed directly, but is obtained as the residual arising out of any imbalance among  
55  
56 644 the other terms” (Frank 1970). It is also possible that other mechanisms that are not  
57  
58 645 addressed directly in this paper may affect the EKE budget, such as the fluxes related to  
59  
60

1  
2  
3 646 the volume displacement (terms 10-12 of Equation 1) and the reanalysis errors in the  
4  
5 647 diabatic processes. Several studies have suggested that the primary effect of latent heat  
6  
7 648 release is to produce a cyclonic PV anomaly in the lower troposphere and an  
8  
9 649 anticyclonic PV anomaly in the upper troposphere (Davis and Emanuel 1991; Stoelinga  
10  
11 650 1996). This relationship is in agreement with earlier investigations (Sakamoto and  
12  
13 651 Takahashi 2005; Garreaud and Fuenzalida 2007; Portmann et al. 2018) which have  
14  
15 652 consistently shown that the latent heat release weakens upper-level COLs. The effect of  
16  
17 653 the mid-tropospheric heating source in COLs is to modify the thermal structure and to  
18  
19 654 result in upper-level divergent flow, then leading to an anticyclonic PV anomaly in the  
20  
21 655 upper troposphere and the system weakening/dissipating. However, if the latent heat  
22  
23 656 source is located in the warm sector of the COLs (for example, on their eastern border),  
24  
25 657 it creates EAPE and we would expect an increase in the upward motion, and  
26  
27 658 consequently an intensification of the COL through the BRC conversion. Similarly, the  
28  
29 659 cloud-top radiative cooling in cold descent regions is expected to increase the EKE  
30  
31 660 (Cavallo and Hakim 2010), resulting in a positive baroclinic conversion rate. As  
32  
33 661 moisture-related processes can modify the vertical structure of potential vorticity,  
34  
35 662 thereby influencing the development of disturbances, errors in diabatic heating in  
36  
37 663 reanalysis could indirectly introduce errors in the EKE budget.

38  
39 664 The accuracy of an estimate of the heating profiles depends on the consistency in which  
40  
41 665 the large-scale circulation and thermodynamic fields are represented in the reanalyses.  
42  
43 666 Particularly, the heating estimates based on the large-scale circulation depends on the  
44  
45 667 estimates of divergence and vertical velocity, which are more susceptible to errors  
46  
47 668 associated with low-resolution data. In the case of diabatic heating based on  
48  
49 669 microphysical processes from reanalysis products, the estimates are more influenced by  
50  
51 670 parameterization of moist processes in the assimilation schemes, which are more  
52  
53  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 671 important in the tropics (Katsumata et al. 2011; Hagos et al. 2012; Ling and Zhang  
4  
5 672 2013). The issues described above could be dealt with more easily by using numerical  
6  
7 673 models, though there are uncertainties in the estimates of diabatic heating profiles by the  
8  
9 674 models. The vertical distribution of diabatic heating is not fairly represented primarily  
10  
11 675 by the models based on convective parameterization, however, using high-resolution  
12  
13 676 numerical models in which cloud microphysics are treated explicitly may be able to  
14  
15 677 simulate moist diabatic processes more realistically. Alternatively, there are methods  
16  
17 678 that can be employed to estimate the diabatic contribution, for example, by using the  
18  
19 679 thermodynamic equation (Caron et al. 2006) or a PV framework (Stoelinga 1996).  
20  
21  
22  
23 680 Therefore, further work is clearly needed to determine how diabatic forcing modifies  
24  
25 681 the dynamics of COLs and their energetics.

26  
27  
28  
29 682 It is worth mentioning that the residual may also be due to computational errors  
30  
31 683 associated with the numerical methods such as the analysis frequency and other  
32  
33 684 unknown mechanisms. In this regard, a part of the uncertainties in the energetic  
34  
35 685 calculations can be overcome by using higher temporal resolution data, such as the  
36  
37 686 ERA5 reanalysis (Hersbach and Dee 2016), to compute a shorter time difference for the  
38  
39 687 LHS of Equation 1. Another problem in most reanalysis systems is the analysis  
40  
41 688 increment added to the background state's fields, thus the analysis increment caused by  
42  
43 689 the changes to the first guess field can result in inconsistencies in the energetic analysis.  
44  
45 690 Simmons et al. (2014) have shown, for example, a temperature analysis increment of up  
46  
47 691 to 0.4 K in the ERA-Interim reanalysis.

48  
49  
50  
51 692 Although compositing is a useful technique to investigate the typical aspects of COLs  
52  
53 693 (Pinheiro et al. 2020b), a better understand of the case-to-case variability in terms of the  
54  
55 694 ageostrophic fluxes and conversions is needed to yield new insights into the different  
56  
57 695 nature of COLs. To deal with the wide variety of development scenarios, an  
58  
59  
60

1  
2  
3 696 investigation of individual cases with respect to their evolution could be considered in  
4  
5 697 future work, perhaps by undertaking a cluster analysis to identify the cases through  
6  
7 698 similarities, or even using the vorticity budget which was found to be less case  
8  
9 699 dependent due to its non-linearity (Azad and Sorteberg 2014).

10  
11  
12 700 This study has addressed some potential questions associated with the COL  
13  
14 701 development, but a key question still remains unresolved: why some COLs lead to  
15  
16 702 surface cyclogenesis and others remain confined at upper levels. The study of Rivière et  
17  
18 703 al. (2015) found that vertical ageostrophic fluxes are important for the redistribution of  
19  
20 704 energy downwards, and the further intensification of extratropical winter storms in the  
21  
22 705 Northern Hemisphere. These vertical fluxes have been checked in this study and their  
23  
24 706 contribution was found to be very small compared to the other terms considered in the  
25  
26 707 discussion above. Further research could investigate the possible mechanisms  
27  
28 708 underlying the deepening of COLs through the vertical modal decomposition in terms  
29  
30 709 of kinetic energy and available potential energy, similarly to Silva Dias et al. (1985).  
31  
32 710 Furthermore, it would therefore be of interest to investigate the possible interaction  
33  
34 711 between COLs and wavetrains of troughs and ridges (wave packets) as the development  
35  
36 712 of upstream systems in geographically remote regions may impact on the local  
37  
38 713 energetics of a COL, as discussed in previous studies (Orlanski and Sheldon 1995;  
39  
40 714 Chang 2000; Wirth et al. 2018).

41  
42  
43 715 The issues discussed here are points that need future research in order to obtain a more  
44  
45 716 realistic view of which mechanisms and environmental factors influence the  
46  
47 717 development of COLs. Despite the issues pointed out above, this study leads to  
48  
49 718 substantial improvements in the knowledge of COLs, contributing to new perspectives  
50  
51 719 on the more relevant influence of the downstream baroclinic development on COLs.  
52  
53 720 This demonstrates that the analysis of various components of the EKE budget combined  
54  
55  
56  
57  
58  
59  
60

1  
2  
3 721 with compositing are useful tools for investigating the evolution of synoptic-scale  
4  
5 722 systems from reanalysis or model datasets.

993 **Figure 1** Trajectories of the 200 most intense Cut-off Lows in the Southern Hemisphere  
 994 identified in both  $\xi_{300}$  and  $Z'_{300}$ . Red lines indicate the trajectories obtained at each 6-  
 995 hourly time step.

996

997

998

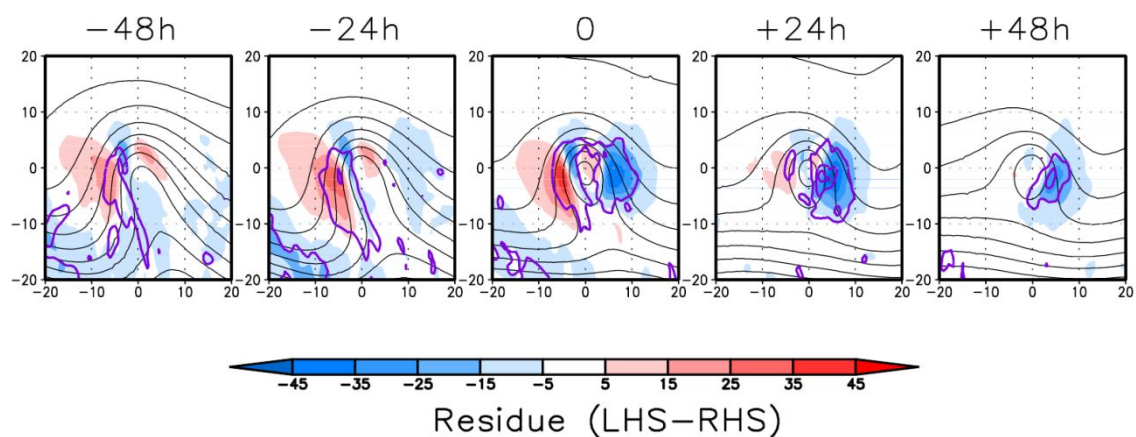

999 **Figure 2** Frequency distribution of the SH COLs for the along-track mean components  
 1000 of the EKE budget: BRC (blue line), BRT (red line), AFC (green line). Fields are  
 1001 vertically averaged within a 15° spherical cap region centered on the COL location. Unit  
 1002 is Joule s<sup>-1</sup>, scaled by 10<sup>10</sup>.

1007  
 1008 **Figure 3** Temporal evolution of the strongest COLs for a) residual and b) total EKE and  
 1009 EKE tendencies. Composites of the 200 most intense SH COLs that match between the  
 1010  $\xi_{300}$  and  $Z'_{300}$ , relative to the time of maximum intensity in  $\xi_{300}$ . Residual values are  
 1011 determined using different spherical cap regions ( $r=5^\circ, 10^\circ, 15^\circ, 20^\circ$  and  $25^\circ$ ) centered  
 1012 on the COL location. The inset indicates the average of residue within the  
 1013 corresponding area. The total EKE and their tendencies are determined within a 15°  
 1014 spherical cap region centered on the COL center. Tendencies are computed using RHS

1  
2  
3 1015 (solid line) and LHS (dashed line). Unit is Joule  $s^{-1}$  for residuals and tendencies (scaled  
4  
5 1016 by  $10^{10}$ ) and Joule for the total EKE (scaled by  $10^{15}$ ). All these quantities are vertically  
6  
7 1017 averaged from surface to 100 hPa.  
8  
9

10  
11 1018

1019

1020 **Figure 4** Temporal evolution of the residue (shaded) and its standard deviation (purple  
1021 line) for the strongest COLs. Composites of the 200 most intense SH COLs that match  
1022 between the  $\xi_{300}$  and  $Z'_{300}$ , relative to the time of maximum intensity in  $\xi_{300}$ . Residue is  
1023 computed by the difference between LHS and RHS of Equation 1. Unit is  $10^{10}$  Joule  $s^{-1}$ .  
1024  $Z_{300}$  height is denoted in black lines for 100 gpm contours.

1025

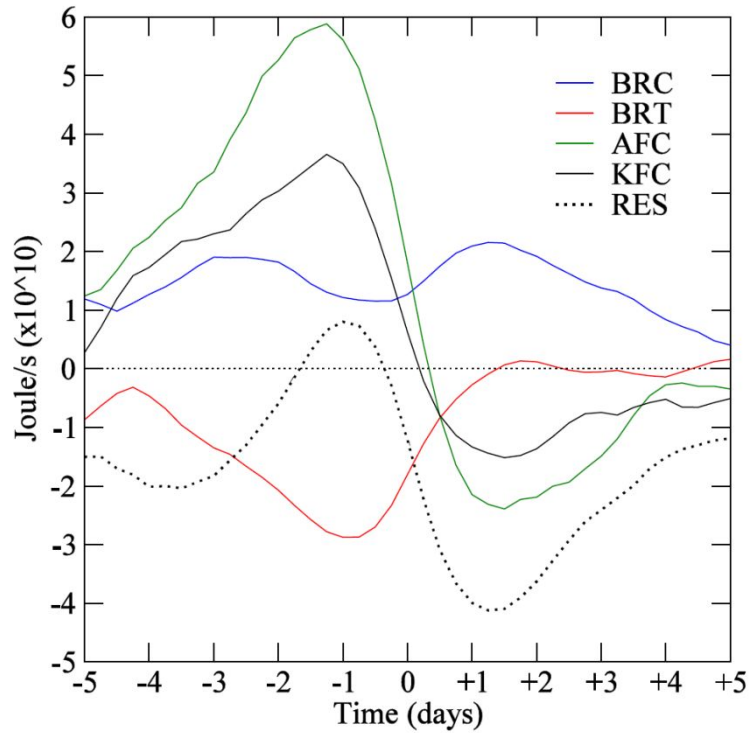

1026

1027

1028

1029

1030

1031 **Figure 5** Temporal evolution of the main EKE terms in the strongest COLs. The terms  
 1032 are BRC (blue line), BRT (red line), AFC (green line), KFC (black line) and RES  
 1033 (dotted line). Fields are vertically averaged within a  $15^\circ$  spherical cap region centered  
 1034 on the COL location. Unit is  $\text{Joule s}^{-1}$ , scaled by  $10^{10}$ .

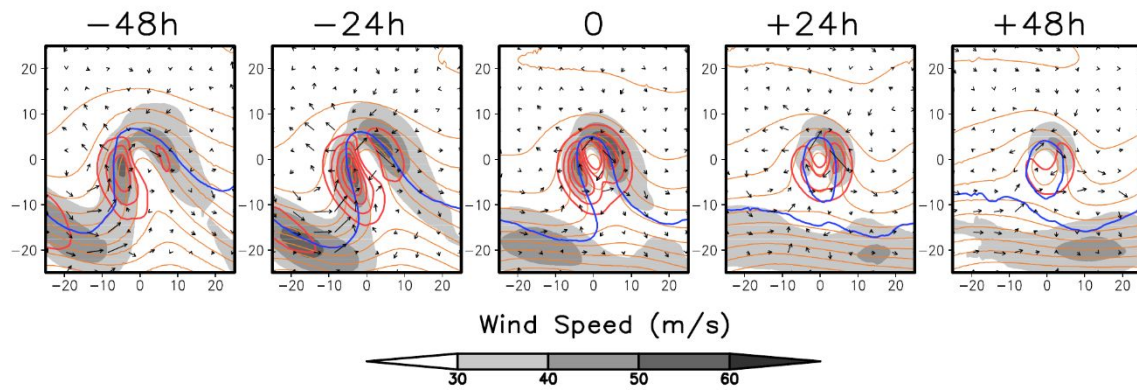

1035

1036

1037

1038

1039

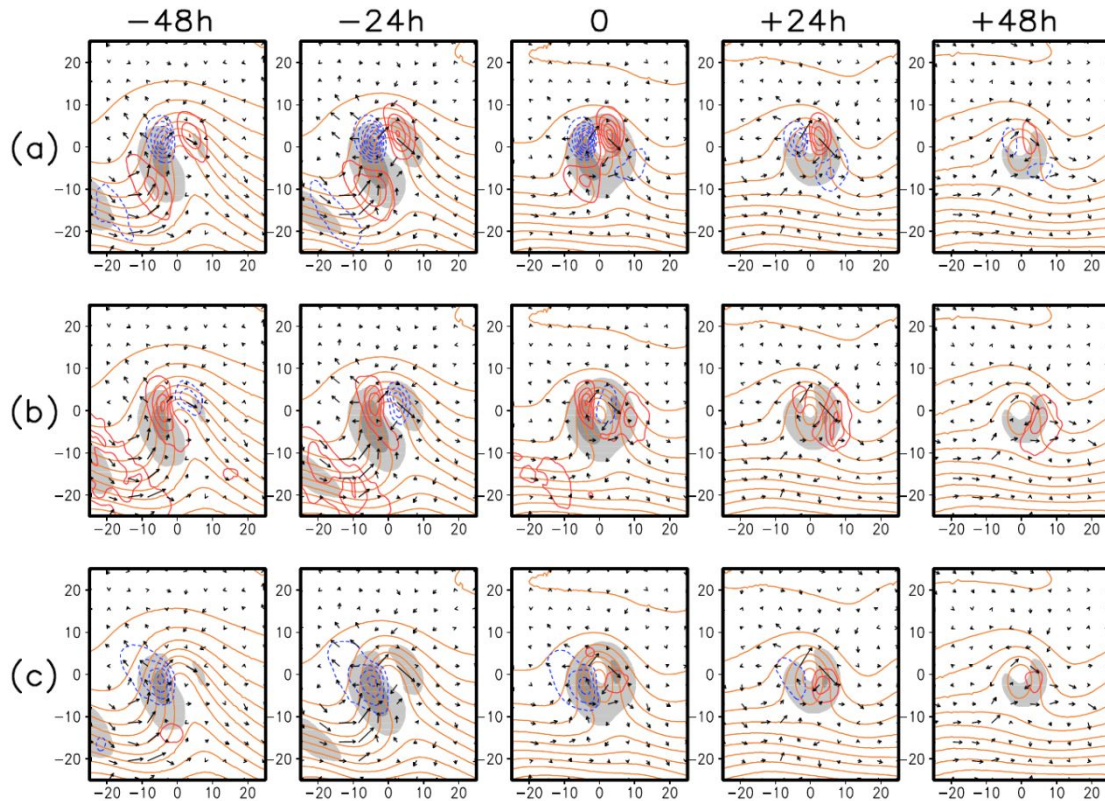

1040

1041 **Figure 6** Temporal evolutions of the 200 strongest Cut-off Lows in the SH that match  
 1042 between the  $\xi_{300}$  and  $Z'_{300}$ , relative to the time and space of maximum intensity in  $\xi_{300}$ .  
 1043 Fields are the total vertically integrated EKE (red line) for  $500 \times 10^{10}$  Joule contours,  
 1044 wind speed in  $\text{m}\cdot\text{s}^{-1}$  (shaded),  $Z_{300}$  height for 100 gpm contours (orange line), -2.0 PVU  
 1045 on the 330 K surface, and integrated ageostrophic fluxes (vectors). The distance from  
 1046 the center of the composite to the edge is  $25^\circ$ .

1047

1048

1049

1050

1051 **Figure 7** Same as Fig. 5 but for the total EKE together with main EKE terms: AFC  
 1052 (upper), BRC (middle) and BRT (bottom). Fields are the total vertically integrated EKE  
 1053 (shaded) for  $1000-1500 \times 10^{10}$  Joule intervals, the  $Z_{300}$  height (orange line) for 100 gpm  
 1054 intervals, combined with vertically average fields of AFC for  $20 \times 10^{10}$  Joule  $s^{-1}$   
 1055 intervals, BRC and BRT for  $5 \times 10^{10}$  Joule  $s^{-1}$  intervals, where positive (negative) values  
 1056 are indicated in red (blue).

# Contributions of downstream baroclinic development to strong Southern Hemisphere Cut-off Lows

Henri Rossi Pinheiro\*, Manoel Alonso Gan, Kevin Ivan Hodges, Sergio Henrique Soares Ferreira, and Kelen Martins Andrade

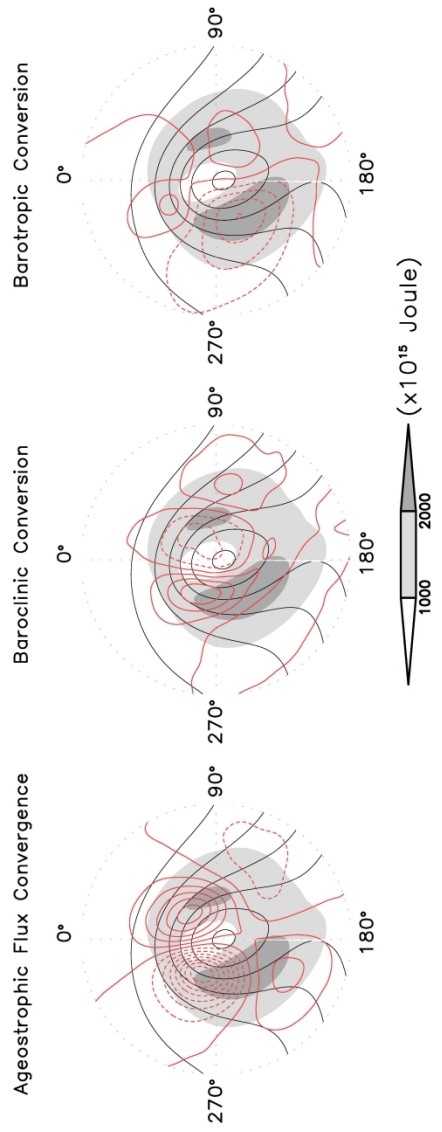

This study provides a new perspective of the main development mechanisms in Cut-off Lows (COLs) by analyzing the relative contributions of the components of eddy kinetic energy budget for the 200 strongest austral COLs. Composite COLs show that the ageostrophic flux convergence (AFC) together with the baroclinic conversion are the most important contributor to the energy growth, characterizing the downstream baroclinic development. The typical development of the COLs involves an interdependent association between the AFC and the baroclinic terms as these processes act by cancelling each other.

(a)

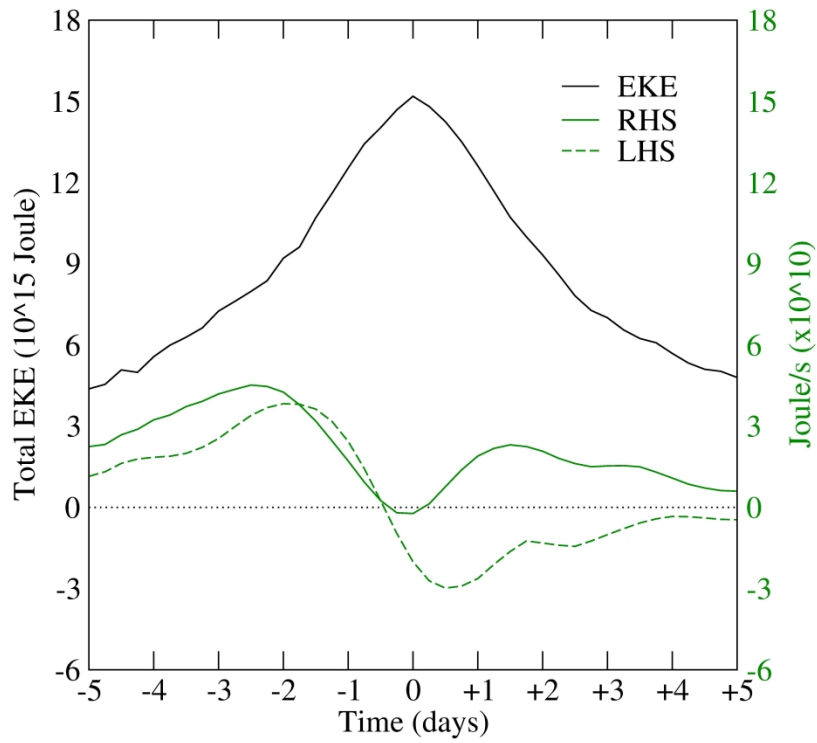

Temporal evolution of the strongest COLs for (a) residual and (b) total EKE and EKE tendencies. Composites of the 200 most intense SH COLs that match between the  $\xi_{300}$  and  $Z_{300}$ , relative to the time of maximum intensity in  $\xi_{300}$ . Residual values are determined using different spherical cap regions ( $r=5^\circ, 10^\circ, 15^\circ, 20^\circ$  and  $25^\circ$ ) centred on the COL location. The inset indicates the average of residue within the corresponding area. The total EKE and their tendencies are determined within a  $15^\circ$  spherical cap region centred on the COL centre. Tendencies are computed using RHS (solid line) and LHS (dashed line). Unit is  $\text{Joule s}^{-1}$  for residuals and tendencies (scaled by  $10^{10}$ ) and Joule for the total EKE (scaled by  $10^{15}$ ). All these quantities are vertically averaged from surface to 100 hPa.
